No. 1. — *An Atlantic "Palolo," Staurocephalus gregaricus.*

By ALFRED GOLDSBOROUGH MAYER.

DURING the summers of 1898 and 1899 I was acting as assistant to Dr. Alexander Agassiz in making a study of Medusæ at Loggerhead Key, one of the Tortugas Islands, Florida; and it was while thus engaged that the remarkable breeding habits of the worm about to be described were observed.

It gives me pleasure to express my appreciation of the generous kindness of Dr. Agassiz, to whose permission I owe the privilege of publishing this paper.

It is also a pleasure to remember the constant interest and kindness of George R. Billbury, Esq., head keeper of the lighthouse at Loggerhead Key, who did everything in his power to further the scientific work, and to render my stay at the Tortugas enjoyable.

I also wish to thank Major J. E. Sawyer, U. S. A., who kindly allowed the use of the government steamer, "George W. Childs," in transporting me and my apparatus to and fro from Key West to the Dry Tortugas.

The worm about to be described in this paper appears to possess breeding habits so closely similar to those of the well-known Palolo worm¹ of the South Pacific that I am inspired to give to it the title of the Atlantic "Palolo." Our Atlantic "Palolo," however, is a new species of the genus *Staurocephalus*, and is therefore quite distinct from the Palolo or Bololo worm (*Palolo viridis*, Gray; *Lysidice viridis*, Collin) of Samoa and Fiji, that swarms in vast numbers, for breeding purposes, upon the surface of the ocean, early in the morning of the days of the last quarter of the October and November moons.

¹ It is not the purpose of this paper to discuss the habits of the Pacific Palolo. Good scientific accounts of its wonderful swarming habit may be obtained from the writings of S. J. Whitmee, 1875; W. C. McIntosh, 1885; A. Collin, 1897; B. Friedlander, 1898; and A. Agassiz, 1898. See "Bibliography" at the end of this paper.

We will first present an account of the swarming of the Atlantic Palolo, and will then give a description of the adult worm, a history of the development of its larva, and finally some general conclusions concerning the breeding habits of Polychætæ.

It seems probable that the time of the swarming of the Atlantic Palolo is directly related to the date of the last quarter of the moon, for in 1898 the swarm occurred on July 9, and the last quarter of the moon on July 10; while in 1899 the worm swarmed on July 1, and the last quarter of the moon fell on June 29. In 1898 about two hundred specimens of the worm were seen to swarm on the morning of July 8, but on the following day the animals appeared in vast numbers, while on July 10 only about a dozen specimens could be found after a careful search. In 1899 a wonderfully dense swarm appeared suddenly on the morning of July 1, and only a few worms were to be seen on July 2, after which they disappeared. As it was my habit to sail out upon the ocean early every morning, I am certain that no other swarms than the above-mentioned ones occurred between June 25–August 19, 1898; and May 17–July 4, 1899.

Description of the Swarming.—The swarming commenced very early in the morning before sunrise, and soon vast numbers of the worms were to be seen swimming upon the surface of the ocean. Few or none of them were to be found in the shallow water near the shore of Loggerhead Key, but at some distance to the westward of the island, where the water was between two and five fathoms in depth, they appeared in astonishing numbers. The bottom at this place is of coral-sand, and is covered with a sparse growth of Gorgonians and Nullipore Algæ, while nearer the shore the bottom consists of living coral and coral-rock with but little sand. When first observed, at four o'clock in the morning of the days of the great swarms, the worms presented very much the appearance shown in Figure 1, Plate 1. They swam with great activity and as near as possible to the surface of the sea. I estimate that there may have been about two worms to each square foot of the ocean's surface. The worms were not uniformly distributed, however, but were scattered irregularly, sometimes congregating momentarily in wriggling masses, such as were likened by Agassiz, in the case of the Fijian Palolo, to "thick vermicelli soup." These congregations are not due to any affinity for one another on the part of the worms, but are merely the result of accident, for each individual worm swims about quite independently of the others, and shows no tendency to remain in the presence of any other which it may chance to meet in its wanderings. The

worms continued to increase in numbers until the time of the rising of the sun, and then, as the light of the early morning fell upon them, a series of contractions came over the sexually ripe segments of each worm and the eggs or sperm were thus discharged into the water (see Figure 2, Plate 1). This contraction is often so sudden and so violent that the ripe segments are torn asunder, at short intervals, by the breaking of the cuticula, forming large rents through which the genital products escape. The 25-30 anterior segments of the worm contain no sexual elements, and take no part in the contraction, so that they remain uninjured, and always retain their natural shape and appearance.

After the discharge of the sexual products the worms continue to swim near the surface for a considerable time, dragging their torn and contracted sexual segments after them. Sometimes, indeed, the contraction causes the sexual segments to break away from the anterior portion of the worm, and they swim about, apparently suffering no inconvenience, although without a head. After the discharge of the eggs or sperm the sexual segments become very brittle, and a touch of the hand is often sufficient to cause them to break suddenly into small fragments. It seems not improbable that the torn and contracted sexual segments may eventually slough off from the 25-30 anterior ones, and that thus the life of the individual may be saved to perpetuate the species. This, however, is mere conjecture upon my part, for in 1898 all of the worms which were confined in aquaria died during the course of the day without having thrown off their dishevelled posterior segments; and in 1899, when four of the worms were placed in a large aquarium the bottom of which was covered with sand and stones, three of the worms crawled under the stones, but all died within two days without having thrown off their contracted sexual segments.

At 6.30 A. M. the worms began to sink down upon the sandy bottom of the ocean, and by nine o'clock in the morning none of them were to be seen. Large numbers of fish devour the worms during the time of swarming.

There is little or no sexual color difference in the worms, both males and females being dull brick-red. The females, however, are sometimes of a duller and more yellowish tint than the males. The sperm is yellow-buff or slightly pink in color, while the eggs are yellow or greenish yellow. The genital products escape in such quantity that the sea is rendered milky over wide areas, and long after the worms have disappeared the eggs remain floating near the surface in visible windrows of yellowish color.

In 1900 the last quarter of the moon occurs on June 19 and July 18; and as we do not yet know the limits of the lunar month in which the worm swarms, we may look for it within three days of either of the above dates along any of the Bahama or Florida reefs. It seems not improbable that it swarms annually on one day of the year, and that this day falls within three days of the moon's last quarter in the month extending from June 15 to July 15.

Description of the Adult Worm. — The genus *Staurocephalus* was founded by Grube, 1855, who has given a synopsis of the genus and a description of all of the then known species in the *Jahres-Bericht der Schles. Gesell. für vaterl. Cultur.*, Bd. 56, pp. 109–115, 1878. Since then two new species have been described by McIntosh ('85, pp. 231–235); and references to previously described species have been given by Ehlers, Verrill, and Andrews.

Generic Characters. — Annelida, Polychæta, Family Nereidæ; body vermiform, segments distinct. The head-lobes give rise to one or two pairs of jointed tentacles. When two pairs of tentacles are present, one pair arises from the side, and the other from the ventral surface. Eyes are sometimes present. The two first segments are without parapodia. The parapodia possess dorsal and ventral cirri. The dorsal cirrus is often unjointed, but sometimes possesses a short terminal segment. The ventral cirrus is shorter than the dorsal and is unsegmented. The posterior segment has two long dorsal and two short ventral cirri. The upper jaw consists of two simple, connected pieces. The lower jaw consists of two rod-like pieces which approach each other near the middle but diverge both in front and behind. (See Figures 20, 22, 26, 27, Plate 3.)

Specific Characters; Adult Worm. — The worm is about 120–150 mm. in length; and may be even longer, for the posterior segment has not been observed. The segments are distinct, and there are about 17 metameres per centimetre of the worm's length. The worm is about 4 mm. broad. The ventral surface is quite flat and a deep groove runs down its centre. The dorsal surface is arched, and the dorso-ventral diameter is about 3 mm. There are no eyes, but the hypodermis cells of the front end of the præstomium bear a dark rosin-colored pigment, the presence of which may indicate a general sensibility to light. There are no lateral tentacles upon the head, but the ventral præstomium gives rise to two quite stiff tentacular cirri (see Figures 1–3, 9–12). These cirri consist each of but a single joint. An axial nerve runs down the centre of each tentacle, and this nerve is surrounded by

elongate hypodermis cells. The first metamere back of the head usually bears a pair of very rudimentary parapodia, each consisting of but a short dorsal and ventral cirrus. (Figures 11, 12.) In the worm shown in Figure 3, Plate 1, the first three segments back of the head bear very minute and undeveloped parapodia. The parapodia of the body segments are all similar each to each and consist in a well-developed dorsal cirrus, a central setigerous lobe, and a ventral cirrus that is shorter than the dorsal. (See Figure 13, Plate 2.) The setigerous lobe bears four kinds of setæ. Most dorsal of all are three or four long curved, slender bristles having a delicately serrated edge (*a*, Figure 4, Plate 1). Immediately below these there are three or four smaller and more slender bristles, having flat spatula-shaped distal ends that exhibit sharp serrations (*b*, Figure 4). The ventral half of the setigerous lobe bears five or six setæ of the sort shown in *d*, Figure 4; and most ventral of all there is a single thick, stiff bristle *c*, Figure 4. The blood of the worm is red, and there is a large red-colored blood sinus at the base of the dorsal cirrus of each parapodium. (See Figure 13.) The 25-30 anterior segments contain no sexual elements, these being found, however, in all of the more posterior segments. The blood vessels and nephridia of the sexually mature segments are much larger than are the corresponding organs in the anterior segments. The nephridia of the sexual segments evidently serve to carry off the eggs or sperm. The nephropores (*np*, Figure 13) are found at the base of each parapodium near the ventral surface. Sections of the worm were made, but the histology is so closely similar to that of other well-known Nereidæ that we consider it unnecessary to enter into details concerning it. The constriction of the sexual segments is due to the powerful contraction of the circular muscles that lie immediately beneath the hypodermis. The sexes are separate, and there is no distinctly marked sexual coloration. The general color of the worm is dull brick-red or ochre-red, and there is a row of diamond-shaped dull white spots, one in each metamere, running down the mid-dorsal line (see Figure 10, Plate 2). Dark brown pigment is found around the orifice of each nephridium (*np*, Figure 13), and there are some indistinct brownish spots on the ventral side of the head (see Figure 12, Plate 2). These are not found, however, in all individuals, and probably do not function as eye-spots.

Development. — The eggs and larvæ were killed in Perenyi's fluid, stained in Kleinenberg's hæmatoxylin, imbedded in paraffin and sectioned, the sections being usually of about 6.6 μ in thickness.

After expulsion from the body of the worm the eggs float near the surface, where they are immediately fertilized. The eggs are quite large; measurements of the embryos in the 16-cell stage gave the diameter 0.36 mm. The segmentation is total and unequal. Four large yolk-laden macromeres are cut off from the four smaller yolkless micromeres. These latter then divide repeatedly and overlap the four macromeres, and thus the gastrula is formed by epibole. Although my observations are far too incomplete for anything but general conclusions, it appears that the early stages of the segmentation are strikingly similar to those of *Nereis* as described and figured by Wilson ('92).

Figure 5, Plate 1, represents an embryo in the 16-cell stage, which occurs about three hours after extrusion into the water. It will be seen that the large macromeres are heavily laden with deutoplasm-spheres, while the protoplasm of the micromeres is finely and uniformly vacuolated, giving the appearance, when seen in sections, of a delicate network. The centrosomes are of large size and stain quite deeply in hæmatoxylin.

Figure 6 represents the condition of an embryo $9\frac{1}{2}$ hours old in which the blastopore (*bp*) is just about to be closed. It will be seen that a distinct segmentation cavity (*scv*) makes its appearance at this stage. This cavity may, however, be due to the action of reagents, and may not represent the natural condition. Unfortunately, all of my material having been killed in Perenyi's fluid, I am unable to make any statements concerning this point. It will be noticed that some of the micromeres at this stage are beginning to exhibit large intracellular vacuoles. This is especially true of those cells about 180° away from the blastopore, and also of some in the immediate vicinity of the blastopore. In later stages this vacuolization affects all of the cells of the embryo, both those of the ectoderm and entoderm, and it is certainly true that for the first week of its life the larva owes its increase in size almost entirely to the remarkable development of intracellular and intercellular vacuoles. In this connection it is interesting to note that Davenport ('97) has shown that in the case of tadpoles the early growth is almost entirely due to the imbibition of water. Soon after this, when the embryo is about $9\frac{1}{2}$ hours old the blastopore closes, and the large deutoplasm-laden cells are completely enclosed by the micromeres. The embryos then become uniformly ciliated and swim about with considerable rapidity.

Figure 14, Plate 2, represents an embryo 24 hours old. Two eyespots are now beginning to appear, and between these there is a collection of greenish-colored cells. These cells stain very deeply in

Kleinenberg's hæmatoxylin, and appear to be filled with a mass of deeply stained granules that may represent the coagulum of some fluid. Figures of these cells, in older larvæ, are shown in (*gl*) Figures 7, 8, Plate 1. I believe them to be glands, and they are probably homologous with the "frontal bodies" found by Wilson ('92, p. 421) in the larva of *Nereis*, and perhaps also with the "problematic bodies" observed by Mead ('97, p. 256) in the larva of *Amphitrite*. Malaquin ('93, p. 395, Plate XIV., Figures 12-16) has also found glands in a similar position in the head of the larva of *Antolytus Edwardsi*.

Figure 15, Plate 2, represents a larva $3\frac{1}{2}$ days old, and Figure 7, Plate 1, shows a dorso-ventral section of the same. The eyes are now quite large, and the green patch representing the gland cells is very prominent. There are now three bands of cilia: a broad oral band, a narrow post-oral, and an anal band. Two sets of setæ, consisting each of three bristles, have made their appearance immediately posterior to the post-oral band of cilia. These setæ originate in folds of the hypodermis. A longitudinal dorso-ventral section (Figure 7) of the worm in this stage shows the very large gland cells (*gl*) of the head. The mouth (*m*) shows signs of being about to break through, although as yet it is not functional. The same may perhaps be said of the anus (*an*). The mid gut (*st*) of the worm now consists of a delicate entodermal epithelium enclosing a mass of highly vacuolated cells laden with yolk spheres.

Figure 16, Plate 2, shows a larva $5\frac{1}{2}$ days old, and Figure 17 illustrates the character of the setæ from the same worm. Most dorsal of all there is a single long seta (Figure 17, *b*) and immediately below this there are two setæ of the sort shown in Figure 17, *a*.

Figure 18, Plate 3, shows a larva 10 days old. The worm is now 0.5 mm. in length, and possesses three sets of setæ. Until the end of the 15th day the larvæ are remarkable for exhibiting a strongly positive phototaxis. They swim through the water at all depths, but large numbers of them are sure to be found clustered together in those parts of the aquaria where the light is strongest.

At the end of the 15th day the cilia disappear, and the worms cease to swim through the water, and sink to the bottom. Figures 19, 20, represent a young worm that is 16 days old, and Figure 8, Plate 1, shows a dorso-ventral longitudinal section of the same. There are now four pairs of parapodia provided with dorsal and ventral cirri. A number of sensory hairs are found scattered over the præstomium, and the posterior segment of the body exhibits a pair of dorsal cirri.

The mouth opens on the ventral surface, and a dorsal and ventral pair of "teeth" have made their appearance in the œsophagus (see Figure 20). The worms are now about 0.8 mm. in length. Internal as well as external evidences of segmentation now appear (see Figure 8, Plate 1) and the dissepiments (*ds*) are complete. The walls of the mid gut are very thick and consist of large, irregularly shaped, highly vacuolated cells containing a number of yolk spheres. The cells of the œsophagus (*oes*) are of an epithelial character. The peripheral circular muscles and the deeper lying longitudinal muscle strands are beginning to appear, and the ventral nerve chain (*n*) is very apparent. In fact, the animal is no longer a larva, but is a young worm.

Figures 21-23, 25-27, illustrate the condition of the worm at the end of the 26th day. There are now five pairs of parapodia, and the dorsal and ventral cirri of the posterior segment have become long and prominent (see Figure 23). The dorsal and ventral jaws of the œsophagus are shown in the side view of the head given in Figure 22. Figures 26 and 27 are views from above and from the side, respectively, of the dorsal pair of jaws. The condition of the ventral pair of jaws is still quite similar to that in the 16-day-old worm shown in Figure 20. The worms are now 1.2 mm. long. They burrow readily beneath the surface of sand, but never swim through the water.

Figure 24 shows the condition of a worm 34 days old. The animal is now 1.5 mm. in length, and there are still only five pairs of parapodia. The mature coloration is beginning to appear in two reddish-colored spots immediately back of the eyes. I did not succeed in rearing any worms beyond this condition, and know nothing of the mode of formation of the præstomium and cephalic cirri of the adult worm. It will be observed that in the young worm the mouth opens on the ventral surface and the præstomium is supra-oral, while in the adult worm the præstomium and cephalic cirri are sub-oral (compare Figures 3 and 22).

General Conclusions.

Remarkably little has been written concerning the egg-laying habits of Polychætæ. Wilson ('92, p. 371) states that the eggs of *Nereis limbata* and *N. megalops* are discharged at night while the animals are swimming upon the surface of the water. The egg-laying season extends at least from June until September. "The animals appear in abundance only on warm still nights, and even then are rarely found

unless the water has been quiet for some days." "When the conditions are favorable, they come forth soon after dark and swim rapidly about at the surface, sometimes in almost incredible numbers."

It would probably be advantageous to any species of worm already possessed of some such egg-laying habits as those of *Nereis* to have the duration of the egg-laying period restricted to as short a time as possible; and also to have it occur in that part of the year most favorable for the safety and development of the larvæ. With equal numbers of mature individuals of two species (*a*) and (*b*), if (*a*) possess a long egg-laying period and (*b*) a short one, there will be more individuals of (*b*) discharging sperm or ova at any given moment than there will be of (*a*), whose breeding season is longer. Consequently the eggs of (*b*) will be more certain of fertilization, other things being equal, than those of (*a*). For example, if N represent the total number of individuals of species (*a*), and also of species (*b*); and if T represent the duration of the egg-laying period of species (*a*) and t that of species (*b*): then in any definite unit of time there will be $\frac{N}{T}$ individuals of species (*a*)

discharging sperm and ova, while at the same time $\frac{N}{t}$ individuals of species (*b*) will be engaged in the same act. Consequently, if the areas of the breeding-grounds of the two species are equal, there will be $\frac{N}{t} \div \frac{N}{T}$ or $\frac{T}{t}$ times as many individuals of species (*b*) discharging sperm or ova at any moment, in a unit of area, than there are of species (*a*) engaged in the same act. Then in an area containing m individuals of species (*a*) there are $\frac{mT}{t}$ individuals of species (*b*). Therefore the

average distance apart of the individuals of species (*a*) is $\frac{\sqrt{\frac{mT}{t}} - 1}{\sqrt{m} - 1}$

times as far as in the case of species (*b*). Hence the spermatozoæ of species (*a*) will be obliged to travel $\frac{\sqrt{\frac{mT}{t}} - 1}{\sqrt{m} - 1}$ times as far as those of

species (*b*). We see, then, that a shortening of the egg-laying season causes a greater concentration of breeding individuals, and therefore shortens the average distance that the spermatozoa must travel in order to fertilize the ova; and as spermatozoa cannot survive for any great length of time, this is an advantage to the species. In this connection

it is interesting to notice that according to Wilson ('92, p. 372) the males of *Nereis* outnumber the females to a very remarkable degree, while in *Staurocephalus gregaricus*, and in the Pacific Palolo, the males and females are about equal in numbers each to each. It is most essential for the perpetuation of the species that the fertilization of the ova should be insured. A very few males placed near to the females will insure this; but where the egg-laying period is a long one, and there are not often great concentrations of individuals, the males must outnumber the females in order to make certain that the ova of any given female may be fertilized.

The egg-laying period of *Staurocephalus gregaricus* occurred in 1898 and 1899 upon days very close to the day of the last quarter of the June-July moon. At this time, in the Tortugas, Florida, the summer is well established, the trade winds are no longer steady or boisterous, and the calm weather that precedes the hurricane season has set in. It is interesting to notice that very similar meteorological conditions prevail in Samoa and Fiji, in October and November, — the months of the swarming of the Palolo.

My friend, Dr. Charles B. Davenport, has called my attention to the fact that the advantages derived from a short egg-laying season are in some measure offset by the circumstance that under such conditions a large number of young larvæ are suddenly produced, and that therefore the struggle for food must be greatly increased. To counterbalance this difficulty, however, we have the interesting fact that while the eggs of *Nereis* contain but little yolk, the eggs of *Staurocephalus gregaricus* are heavily laden with yolk material.

When we learn more concerning the egg-laying habits of Annelids, there will no doubt be a number of species found that possess such swarming habits as those of *Nereis*, and perhaps a few may be discovered in which the breeding season is as short as in *Staurocephalus gregaricus* and *Palolo viridis*. In 1893, while acting as assistant to Dr. Alexander Agassiz upon the "Wild Duck" Expedition to the Bahama Islands, I had the opportunity of observing the swarming of an Annelid. We were anchored off Watlings Island (San Salvador) on the night of January 15, and in Clarence Harbor, Long Island, on the night of January 16. On both of these nights the surface of the sea was covered by thousands of little Annelids. They were translucent, and had large red eyes. They appeared to be congregating for breeding purposes, and were breaking into pieces, so that we often found fragments 50 mm. in length swimming about without a head. The last quarter of the moon

occurred on January 9, 1893, and their swarming probably had no relation to this event.

Among worms, where certain segments of the body became sexually mature while others remain immature, or non-sexual, we find an interesting series of gradations in complexity. Beginning with *Staurocephalus gregaricus*, where the sexual and non-sexual segments are exactly alike in external appearance, and where the entire worm swims at the surface at the breeding period, the next advance in complexity is met with in *Palolo viridis*, where, according to Friedlander (1898) the non-sexual segments are very different in appearance from the sexual, and where the sexual segments break off from the anterior portion of the worm and swim about during the egg-laying period without a head. Most complex of all are the cases of *Autolytus*, *Filigrana*, *Myriana*, *Proceræa*, *Syllis*, etc. (see A. Agassiz, '62; Malaquin, '93, etc.), where the sexual segments acquire a head, and eventually become free swimming worms, thus producing an alternation of generations.

It seems probable that *Staurocephalus gregaricus* and *Palolo viridis* have independently acquired quite similar breeding habits through the agency of similar influences of natural selection; although it must still be admitted that there remains a possibility that both worms may have descended from a remote and common ancestor that possessed some such breeding habits.

The following table will serve to illustrate the principal points of relationship in the breeding habits of the two worms:—

THE ATLANTIC "PALOLO."

Staurocephalus gregaricus, MAYER.

On July 9, 1898, and July 1, 1899, the worm swarmed in vast numbers, for breeding purposes, at the Dry Tortugas Islands, Florida. The last quarter of the moon occurred on July 10, 1898, and June 29, 1899.

The 25-30 anterior segments of the worm contain no sexual elements, the eggs or sperm being found in the posterior body segments. The anterior segments, how-

THE PACIFIC PALOLO.

Palolo viridis, GRAY, 1847.
Lysidice viridis, COLLIN, 1897.

The worm swarms in great numbers, for breeding purposes, at Samoa and Fiji, upon the mornings of the day of, and the day preceding, the last quarter of the October and November moon. (See Whitmee, 1875; Friedlander, 1898.)

According to Friedlander, 1898, a number of the anterior segments of the worm contain no sexual elements, these being found in the posterior body segments. The anterior seg-

ever, are similar to the sexually developed posterior ones in external appearance.

The entire worm swims at the surface during the breeding period.

The eggs or sperm are extruded from the sexual segments by a series of contractions. They pass out into the water not only through the nephridial openings, but also through rents and tears in the body wall of the worm, which are often produced by the violence of the contractions. This action usually occurs soon after sunrise.

There is no well-marked sexual color difference, both males and females being brick-red, or ochre-red. The eggs are greenish-yellow and the sperm buff-pink.

The males and females are about equal in number each to each.

The segmentation is total and unequal, and the gastula is formed by epibole. The larva is telotrochal. The setæ appear very early in development. The larva possesses a pair of eyes, and remarkably large ectodermal, cephalic glands.

HARVARD UNIVERSITY, April, 1899.

ments are of greater breadth and less length than are the sexually developed posterior segments. (See Figure by Friedlander.)

The posterior or sexual segments, only, swim at the surface during the breeding period. The anterior portion of the worm remains below.

The eggs or sperm are extruded from the sexual segments by a series of violent contractions. They pass out into the water not only through the nephridial openings, but also through rents and tears in the body wall of the worm, produced by the violence of the contractions. This action usually occurs soon after sunrise. (See McIntosh, 1885 ; A. Agassiz, 1898.)

The males are brown, and the females dark green. The eggs are green. (See Whitmee, 1875 ; McIntosh, 1885.)

The males and females are about equal in number each to each.

The development is unknown.

¹ Contributions from the Zoölogical Laboratory of the Museum of Comparative Zoölogy at Harvard College, E. L. Mark, Director, No. 112.

I. INTRODUCTION.

IN the fall of 1897 a small leech, which is very abundant in the ponds about Cambridge, Massachusetts, was selected as an object for study in the class in Microscopical Anatomy in Harvard University. This selection brought under my observation a rather large number of leeches living or prepared in one of various ways, and gave occasion to the studies out of which this paper has grown. The kindness of friends has greatly aided me in obtaining material. In this connection my thanks are due to Mr. G. M. Allen, who sent me living leeches from the White Mountains in New Hampshire and also collected for me much valuable material in Massachusetts; to the Museum of Comparative Zoölogy for the privilege of studying its collection of leeches; to Professor James G. Needham, who sent me collections made in New York and Illinois, and also loaned me for study the collection of leeches belonging to Lake Forest University; to Dr. C. A. Kofoid, who obtained for me leeches from Havana, Illinois; to Mr. R. H. Johnson, for specimens collected in Lake Chautauqua, N.Y.; and last but not least, to Professor E. L. Mark and Dr. Otto Zur Strassen, who collected and preserved for me individuals of several European species.

Professor Whitman, who has given so much attention to the study of leeches, several years ago ('91^a) pointed out the inadequacy of all descriptions then existing of our North American species of "Clepsine," showing that the descriptions in question were based on characters altogether too superficial and unreliable. Whitman himself presented a model in his description of "*Clepsine plana*;" but as this has not been followed by any similar account of our other species, I have thought it worth while to record in this paper some observations of my own, together with the views regarding the external morphology and relationships of our common species, to which studies, chiefly anatomical, have led me.

II. METHODS.

For the study of the general anatomy of a leech and particularly for the study of its external morphology, it is important to have both living animals and those which have been killed in a good state of extension. Of the former I have been fortunate enough to obtain an abundance; in preparing the latter I have found very serviceable the method recom-

mended by Lee ('94, p. 17) of stupefying with carbonated water.¹ The animals are placed in a Stender dish and covered with water from a "soda siphon." As soon as they are thoroughly stupefied, they should be quickly transferred to the killing fluid, which is best used warm, not boiling hot, but heated to about 70°C. A stay of from two to five minutes in the carbonated water usually suffices to stupefy the smaller species enough for successful fixation, and indeed is better than more prolonged treatment. For if the animal still possesses a slight degree of irritability, it will usually straighten out in the warm killing fluid and die in a better state of extension than it was in before. The large species require a much longer treatment with the carbonated water. The best reagent to use in killing animals for whole preparations is, in my experience, Perenyi's fluid, which leaves the animal well extended and renders it clear and transparent. It has the property of removing pigment from the body, particularly the darker sorts of pigment. For instance, I have noticed that in killing the beautifully variegated *Glossiphonia parasitica* with this fluid, the green and brown spots often disappear entirely; while the yellow and orange spots remain conspicuous. This quality is sometimes an advantage, sometimes a disadvantage. If one wishes to preserve the color-pattern unimpaired, he would do well to use a fluid containing picric acid, which seems to have the property of fixing the pigment; or, better still, use formaldehyde both as the killing and as the preserving fluid.

Flemming's fluid is perhaps, on the whole, the best fixing fluid to use in preparing sections; corrosive sublimate is also good; Perenyi's fluid is for this purpose not to be recommended, except for the study of the gross anatomy of the central nervous system, which it makes very clear by bringing out nerves and fibre tracts in strong contrast to their connective-tissue sheaths.

Iron hæmatoxylin is the best stain which I have tried for sections. For whole preparations, animals should be heavily stained with carmine and then pretty thoroughly decolorized. I find Mayer's hydrochloric acid carmine (70% alcoholic) very convenient and serviceable, as it stains powerfully and there is no danger of maceration of tissues, however long the stain is allowed to act.

Decolorizing is best done with alcohol pretty strongly acidulated, as greater contrasts are thus obtained. I use 1% hydrochloric acid in 70%

¹ This method of stupefaction is also very useful in the study of the living animal, for the leech may be kept entirely motionless in the carbonated water within a live-box for hours, and then be revived by placing it again in fresh water.

alcohol, allowing it to act until the specimens have a light rose color, then wash well in neutral alcohol (90%), clear in cedar oil, and mount in balsam.

III. CLASSIFICATION.

Leeches of the family Rhynchobdellidæ may be distinguished from all others by the fact that they possess an exsertile proboscis (*pr'b.*, Figure 1), with the aid of which they obtain their food, for they are entirely without jaws such as the medicinal leech possesses. Our common North American species of this family belong to the genus *Glossiphonia* Johnson ('16), better known to many by its synonym *Clepsine* Savigny ('20). Leeches of this genus have usually a broad flat body, which, when the animal is disturbed, is rolled into a ball. Each somite consists typically of three distinct rings; but the somites at the ends of the body always contain a smaller number of rings.

These leeches are found in the shallow water of ponds and rivers underneath stones, sticks, or leaves, or adhering to the bodies of their hosts. The smaller species feed upon snails, crustacea, or other small fresh-water animals; the larger species are known to feed upon turtles, to whose shells they are often found attached. They probably suck the blood of other aquatic animals also.

The following key may aid in distinguishing the species to be described:—

Key to Species.

- A. Crop diverticula a single pair (after a full meal the animal may have five more pairs, inconspicuous, and situated anterior to the principal pair); male and female genital pores separated by a single body ring; rings without metameric markings in the living animal.
 1. Eyes two, distinct; a conspicuous yellowish brown chitinous spot on the neck dorsally *G. stagnalis* (p. 21)
 2. Eyes two, inconspicuously pigmented or entirely without pigment; no chitinous spot on the neck; body extremely slender and transparent *G. elongata* (p. 39)
- B. Crop diverticula six pairs; male and female genital pores separated by a single body ring or else united.
 3. Eyes two, the middle (sensory) ring of each somite marked throughout the greater part of the body by a transverse row of whitish spots *G. fusca* (p. 34)

4. Eyes six, the first pair small and close together, the others farther apart; rings without metameric markings, or with dark pigment on the *anterior* ring of each somite.

G. heteroclita (p. 42)

C. Crop diverticula seven pairs; male and female genital pores separated by two body rings.

5. Eyes six, distinct, in two parallel rows; a conspicuous longitudinal band of dark pigment on either side of the median plane dorsally, and a fainter one ventrally; inconspicuous papillæ on the dorsal surface *G. elegans* (p. 46)

6. Eyes apparently a single pair, far forward on the head and confluent; back distinctly papillose. A large species, often found on turtles *G. parasitica* (p. 51)

IV. DESCRIPTION OF SPECIES.

1. *Glossiphonia stagnalis* LINNÆUS (1758).

Plate 1, Figs. 1, 3; Plate 2, Fig. 4; Plate 3, Figs. 7-10, 12; Plate 8, Fig. 34.

Hirudo stagnalis Linnæus (1758); *H. bioculata* O. F. Müller (1774); *Clepsine bioculata* Savigny ('20); *C. modesta* Verrill ('72); *C. submodesta* Nicholson ('73).

a. HABITAT, FORM, SIZE, COLOR.

This species is found in Europe, the adjacent parts of Asia and Africa, and in North and South America. As one might expect in the case of so cosmopolitan a form, much has been written about it, but its external morphology has never been carefully and accurately analyzed, and published accounts of its internal anatomy contain a number of errors or omissions, some of which I hope to rectify.

The general form of the body as seen in dorsal view, when partially extended, is shown in Figures 1 and 4. The body is broadest posterior to its middle and thence tapers gradually toward both ends. The head, which is only slightly wider than the neck, is evenly rounded in front (Figure 3); dorso-ventrally the body is very much flattened, especially when at rest. The animal is very active in its movements and can greatly elongate its body so as to become more than ten times as long as it is broad. The largest individuals measure as follows:—

Length, fully extended, 20-25 mm.; at rest, 8-10 mm.

Width, fully extended, about 2 mm.; at rest, about 5 mm.

Color, flesh-color or grayish. Small individuals are usually quite clear and transparent, but larger ones are apt to be more or less opaque. This opacity,

as well as the general grayish tint which the body often has, is due to the presence in varying proportions of two different sorts of pigment cells. Those of one kind, which might properly be called reserve-food cells, may be found in the deeper parts of the body of all well-nourished individuals. They are large rounded cells, with an excentrically placed nucleus, their cytoplasm being filled with rounded, highly refractive granules often nearly as large as the nucleus. By reflected light these granules appear of an orange-brown color. Osmic acid browns slightly, but does not blacken them. Corrosive-acetic or picro-nitric mixtures make their composite nature apparent. An outer shell of darker, brownish substance appears surrounding usually one, sometimes two or three perfectly clear spherical inclusions. Perenyi's fluid, which is very strong in nitric acid, if allowed to act for about an hour, destroys almost every trace of the granules, the outer shell being the last part to disappear. Absolute alcohol acts in a similar way, but more slowly.

Graf ('99) has figured the granules accurately (see his Figures 87 and 102), but interprets their structure somewhat differently, regarding the clear portions as cavities; hence he speaks of the granules containing them as ring-shaped structures.

I at first supposed the clear portion to be a central core unaffected by the killing fluid, but abandoned this idea when I discovered two or more of them in different parts of the same granule. It seems to me that the outer part of the granule, which possibly contains some fatty material, as the osmic acid test indicates, is laid down upon a central core of a different substance which dissolves much more readily in acid solutions. So much my preparations indicate, but do not prove conclusively. Further study should be given to these interesting structures, doubtless a reserve-food product, which reminds one of the structures found in the seed of the Castor-oil Bean (*Ricinus*).

The second sort of pigment cell found in this species belongs to Graf's ('99) category of "excretophores." They occupy a superficial position in, or just under, the epidermis, and are slender, thread-like, branched (structures) of a dark-brown color. They are especially abundant in animals which have been kept for some time in well-lighted aquaria. Graf believes that pigment cells of this sort become detached as leucocytes from the wall of the body cavity, take up excretory products in the deeper parts of the body, especially in the neighborhood of the blood vessels, and then by amœboid movements make their way to the surface of the body, there to disintegrate.

b. RINGS, SOMITES, EYES.

External rings, rounded and distinct; sixty-seven in number, counting two narrow rings at the posterior end of the body (64 and 66, Figure 4, Plate 2).

Somites, thirty-four, as in all species of *Glossiphonia*. Somites VI.-XXIV., triannulate (Figure 4); all other somites show more or less abbreviation.¹

¹ Throughout the descriptive part of this paper I shall speak of those somites which contain fewer than three distinct rings as "abbreviated" or "reduced." I

Somites I. and II. are together represented by a single broad ring (Figures 3, 4), which, however, is sometimes subdivided by a shallow furrow (Figure 7, Plate 3).

Somites III. and IV. consist each of a single ring, the latter forming the posterior boundary of the oral sucker (Figure 3, Plate 1; Figure 7, Plate 3).

Somites XXV. and XXVI. consist each of two rings, a broad followed by a narrow one (63 and 64, 65 and 66, Figure 4, Plate 2; Figure 34, Plate 8). The narrow ring of somite XXVI., however, is often so completely fused with the broader ring which precedes it as to be scarcely distinguishable.

Somite XXVII. consists of a single broad ring, crowded back to a position lateral and posterior to the anus (67, Figures 4, 34, and A).

Somites XXVIII.-XXXIV. are not represented by external rings; in the central nervous system, however, we shall find clear evidence of their separate existence. A further discussion of the metamerism will be deferred until the nervous system has been described.

Eyes, two, large and distinct, lying in the anterior part of ring 3 and extending forward into the posterior part of ring 2 (Figures 4, 7).¹

c. DORSAL GLAND, SUCKERS.

Dorsal Gland. — Between the twelfth and thirteenth rings (that is, between the anterior and middle rings of somite VIII.) on the mid-dorsal surface of the animal, is a structure (*gl. d.*, Figures 4, 7) peculiar to this species, though according to Apáthy ('88^a) its homologue is found in some other species, either as a functional structure in the embryo, or as an inconspicuous rudiment in the adult. It consists of a rounded, wart-like, yellowish-brown, cuticular plate, often surrounded by a ring of substance similar but lighter in color, probably because less well hardened. These structures are secreted by a patch of high columnar epidermal cells, which in the embryo, according to Apáthy, form a sort of byssus gland serving to attach the young to the under side of the mother before the suckers at the ends of the body become functional. In the adult the organ has no known function, though it forms a favorite place of attachment for a certain colonial protozoön of the genus *Epistylis*.

do so, however, without feeling at all certain that the terms are strictly applicable in all cases or even in a majority of cases. I have elsewhere (Castle, 1900) expressed the opinion that the leech somite consisted primitively of a single ring. If this is so, it may well be that the somites commonly spoken of as abbreviated have really never attained the triannulate condition. (Moore, 1900, has expressed a similar view since this paragraph was written.) Nevertheless the term is a convenient one to express deviation from the typical condition of the somite in the direction of a shortening of it. In this sense the term will be employed in this paper.

¹ Budge ('49) likewise represents the eyes in the anterior part of ring 3. Apáthy ('88^a), however, counts the ocular ring the fifth, emphasizing subdivisions which can occasionally be seen in the most anterior rings. (Compare his Figures 4 and 10 with my Figures 3 and 7.)

The *oral sucker* (*suc. or.*, Figure 7) lies on the ventral side of the head, within the limits of rings 1-3 (somites I.-IV.).

The *mouth* (*or.*, Figure 7) opens anterior to the middle of the oral sucker as well as anterior to the eyes.

The *posterior sucker* (*act.*, Figures 1, 4), also ventral in position, is slightly longer than broad. Average dimensions for the largest individuals are:—length, 1.31 mm.; width, 1.24 mm.

d. REPRODUCTIVE ORGANS.

The *male genital pore* (*po. ♂*, Figure 4) lies in a mid-ventral position between rings 24 and 25; that is, between the anterior and middle rings of somite XII.

The *female genital pore* (*po. ♀*, Figure 4), which is a broad transverse slit, lies just one ring behind the male pore, between rings 25 and 26, the middle and posterior rings of somite XII.¹

Testes (Figure 4, *te.*), six pairs, placed intersegmentally in somites $\frac{\text{XIII.}}{\text{XIV.}} - \frac{\text{XVIII.}}{\text{XIX.}}$.

The size and appearance of the testes vary considerably with the seasons. In the fall and early spring they are generally large and their outlines more or less irregular, for they adapt themselves to the spaces left them among the dorso-ventral muscles and other deep-lying organs. The testis wall is quite thick on its dorsal, ventral, and lateral aspects, but somewhat thinner on its median aspect. It is lined with a loose germinal epithelium of spindle-shaped cells, except at its dorso-median angle, where there is a small patch of ciliated epithelium continuous with that of the vas efferens.

Male genital ducts.—The vas efferens is a short, delicate tube, which leads dorsad and cephalad to join a longitudinal duct similar in structure to itself and only slightly larger, the proximal or collecting part of the vas deferens (Figure 4, *va. df.*). Anterior to the first pair of testes, that is, about on the border between somites XII. and XIII., the collecting portion of the vas deferens bends sharply toward the median plane of the body and passes between the strong dorso-ventral muscles, which, like a row of pillars, mark off on each side the

¹ I am unable to find in any published account an explicit statement as to the position of the genital pores in this species. Budge ('49) figures the male pore in the posterior third of ring 25 and says, "Gegen den 25 Ring findet sich die sehr feine männliche Geschlechtsöffnung." He does not figure the female pore, but says (p. 100), "Ungefähr am 27. Leibesringe die äussere [female] Geschlechtsöffnung liegt." This would make the genital pores distant from each other about two rings, which, however, is incorrect.

Ludwig ('86) incorrectly describes the position of the genital pores for the entire genus "Clepsine" as follows (p. 781) "männliche Geschlechtsöffnung zwischen dem 25. und 26., weibliche zwischen dem 27. und 28. Ringel." This statement rests upon two erroneous assumptions, first, that the number of distinct rings is the same in the head region of all species, and, secondly, that the genital pores are always two rings apart. In only two of the six species described in this paper are the genital pores separated by two rings.

lateral limits of the median lacunar space. This space the vas deferens enters in company with the ducts of the salivary glands, which here pass inward to join the base of the proboscis (Figure 1, *gl. sal.*) Having reached the median lacuna, the vas deferens turns backward, running usually ventral and lateral to the digestive tube and parallel with the course of its collecting portion. In the median lacuna it winds about more or less, or may even cross into the opposite half of the body as a result of its being crowded for room either because of its own distended condition or from the condition of other organs in its vicinity. As it runs backward it widens into a spacious seminal vesicle (Figure 4, *vs. sem.*), and its epithelial lining ceases to be ciliated. The dimensions of the seminal vesicles vary with the amount of sperm stored in them, being capable apparently of great enlargement. Sometimes the vesicle runs back as far as the pair of long crop diverticula in somite XIX. (Figure 1), and is crowded out in the form of one or more loops between the testes (Figure 4); it may even find room for itself by crossing into the opposite half of the body. Ultimately it bends forward again and, narrowing, continues as the muscular and glandular ejaculatory duct (Figure 4, *dt. ej.*). The ejaculatory duct, as it runs forward, passes outside of the inner row of dorso-ventral muscles at about the point where the collecting portion of the vas deferens enters the median lacuna. It then runs forward into somite XI., where, turning sharply back again, it expands into a thick-walled "terminal horn," which, uniting with the terminal horn of the other half of the body, opens to the outside by the mid-ventral male genital pore (*po. ♂*, Figure 4). The special function of the ejaculatory duct and particularly of its terminal horn, Whitman ('91) has shown to be the formation and extrusion of the spermatophore.

In the early spring, as the water in the ponds begins to grow warmer, the seminal vesicles are seen to be gorged with sperm, and the formation of spermatophores takes place rapidly. These the animals attach to one another's backs. Whitman ('91) has shown that in the case of *G. parasitica* ("Clepsine plana") the contents of the spermatophore pass through the integument into the body cavity, and that impregnation probably occurs while the egg is still in the ovary. A similar process doubtless occurs in the case of *G. stagnalis*.

After the period of active spermatophore formation has passed, — it ordinarily lasts but a few days or weeks, depending upon the rapidity with which the temperature of the water rises, — the vasa deferentia are seen to be greatly reduced in size and the testes quite inconspicuous, though in the fall they were the most conspicuous organ in the entire body.

The ovaries (Figure 4, *oa.*) are a pair of simple sacs extending back from the female genital pore in the median lacuna, usually ventral and lateral to the digestive tube. They are attached more or less loosely by mesenterial strands of connective tissue to those portions of the vasa deferentia which lie in the median lacuna. This connection, however, is so slight that when crowded for room an ovary may extend out in loops between the testes, or across into the opposite half of the body, just as the vasa deferentia do. The size of the ovaries depends upon the state of maturity of the contained ova. They are

largest in the early spring immediately before the eggs are laid, when they often extend the whole length of the genital region and are looped or folded, as are the seminal vesicles; they are smallest immediately after the egg-laying. A mean between these two extreme conditions is shown in Figure 4.

The time of egg-laying, as well as of spermatophore formation, depends upon the warming of the water in the spring. One can hasten both processes by bringing the animals for a few days into a heated room. Around Cambridge the eggs are laid mostly in the months of April and May. Small-sized individuals, however, may come to maturity later in the season, even as late as September.

The eggs are pink in color and about 0.3 mm. in diameter. They are attached to the under surface of the body in groups of two to eight eggs each. Each group is enclosed in a separate, delicate, transparent sac, which adheres to the under surface of the body. The sacs are arranged in two longitudinal rows close together, one on either side of the median plane of the body. The more posteriorly placed sacs usually contain more eggs than those farther forward.

I have not observed the process of egg-laying, but believe that the eggs of a single sac are laid at about the same time, that they are then crowded back as far as possible under the body, and that there is poured over them a secretion from the clitellar glands which hardens into the delicate wall of the sac. After a period of rest, during which the body is closely applied to the group of eggs so that its sac becomes fastened to the body, another group of eggs is laid, and so on until all the mature eggs have been expelled from the ovary. The clitellar glands are deep-seated, unicellular epidermal glands opening on the ventral surface in the vicinity of the female genital pore. They can be demonstrated by methylen-blue staining.

Animals which are kept in aquaria lay their eggs at night, and always complete the process in a single night, so that all the eggs borne by an individual are in about the same stage of development at one time.

I think it probable that the egg sacs are arranged in the order laid, from behind forward, for in one of the most anterior sacs a single egg is occasionally found, but never in one of the more posterior sacs have I observed so small a number. The number of eggs laid by an individual depends upon its size. An animal thirteen mm. long (when fully extended) was found to have laid sixteen eggs; another twenty-six mm. long was found carrying forty-five eggs. The average number for nine individuals examined at one time was thirty-one.

The usual number of egg sacs formed is six or eight; in one case examined it was ten. The average number of eggs found in a sac is about four; for the most anterior pair of sacs it is three.

e. DIGESTIVE TRACT.

The position of the *mouth* (or, Figures 3, 7), except when the body is much contracted, is anterior to the eyes, in the third somite (ring 2).

It leads dorsally into the *pharyngeal sac* (*sac. phy.*, Figure 7), which con-

tinues backward through the brain mass, ending in somite XIII. (Figure 1). Within the pharyngeal sac lies the *proboscis* (*pr'b.*, Figure 1), which, in a state of rest, usually extends from a point just behind the brain back into somite XIII., where the ducts of the *salivary glands* enter its walls. These glands (*gl. sal.*, Figure 1) are a conspicuous feature of a *Glossiphonia* differentially stained. They are always unicellular, and represent the largest cells found in the body except certain nephridial cells and eggs approaching maturity. The salivary gland cells have a great avidity for stains. They number in this species thirty or more in each half of the body, and are found scattered through about three somites (XII.-XIV.). The largest gland cells are those most remote from the base of the proboscis. Each cell has a separate slender duct leading into the wall of the proboscis and opening into the lumen of that organ at some point along its length.

A short slender *œsophagus* (*œ.*, Figure 1), ordinarily lying entirely within somite XIII., connects the base of the proboscis with the *crop* (*i'glv.*, Figure 1). This readily distensible part of the digestive tract extends over six somites (XIV.-XIX., Figure 1). *Under ordinary circumstances it has but a single pair of lateral diverticula*; these arise in somite XIX. and extend backward, usually ending in somite XXI. After a full meal, however, short lateral diverticula may sometimes be seen also in the five more anterior somites (XIV.-XVIII.), but this condition appears always to be a transient one.

The *stomach* (*ga.*, Figure 1) begins in somite XX. and ends in somite XXIII. It bears four pairs of persistent lateral diverticula doubtless originally segmental in origin, but now crowded within the limits of about three somites. The first two pairs of stomach diverticula are directed forward, the last pair backward; the third pair lies about at right angles to the long axis of the body.

The terminal part of the digestive tract, the *intestine* (*in.*, Figure 1), is a gradually narrowing tube; it includes one or two proximal chambers separated from the following part by constrictions.

The anus is dorsal in position, as in all other leeches, and lies within or just behind somite XXVII. (Figure 4, page 32; Figure 34, Plate 8). Comparison with other species, in which the reduction of somites is less extensive, shows that primitively the anus lay *behind* somite XXVII.

f. NEPHRIDIA.

The nephridia number at least sixteen pairs, possibly seventeen pairs. The nephropores (*nph'po.*, Figure 4) lie on the ventral surface of the body, somewhat nearer the margin than the median plane, and almost exactly in the middle of their respective rings. The nephropores are always found in this genus on the middle ring of a somite. I have found them in sections of *G. stagnalis* in somites VIII.-XXIV., with the single exception of somite XIII. (ring 28). The strong development of the salivary glands in this region may account for the possible disappearance of the pair of nephridia which we should expect to find here.

g. NERVOUS SYSTEM.

The central nervous system, as in other leeches, consists in the middle part of the body of a ventral ganglionic chain of twenty-one distinct ganglia metamERICALLY arranged and joined by paired connectives. Forming an extension of this ganglionic chain at either end of the body, one finds a nervous mass representing several primitively distinct ganglia more or less intimately fused together. In the central part of the body the ordinary position of the nerve ganglion is in the middle ring of its somite (Figure 4, somites XII.-XVIII.). Toward either end of the body, however, there is a slight, but increasing, centripetal displacement of the ganglia, just as is frequently the case in the central nervous system of Arthropoda. This displacement may amount to as much as two-thirds of a somite, or in extreme cases an entire somite. Thus we see in Figure 4 that the ganglion of somite VII. lies in the first ring of somite VIII., a displacement of two rings; in somites VIII.-XI. the displacement is only a single ring. About the same amount of displacement occurs in somites XIX.-XXII.; in somites XXIII. and XXIV. it amounts to about two rings; and in somites XXV.-XXVII. it is still greater. The positions in which the nerve ganglia are shown in Figure 4 are average ones carefully computed from the observed positions in five different individuals. The ganglia are very constant in position, the extreme variations usually amounting to only a fraction of the width of a ring.

The structure and morphological value of the ganglionic masses at the two ends of the body is a subject closely connected with the general question of the metamerism of the body.

h. METAMERISM.

(1) *Number of Somites.*

A number of investigators have discussed the question of how many somites are found in the body of a leech, and have reached conclusions varying according as they placed emphasis on one or another of the following criteria: (1) The number of external rings; (2) color markings of rings, or the recurrence of peculiar papillæ on certain rings of each somite; (3) metameric sense organs; (4) the number of ganglia in the central nervous system as determined (*a*) by a count of the nerve capsules, typically six to a ganglion, or (*b*) by ascertaining the number and peripheral distribution of the nerves arising from the ganglia.

Whitman ('92), making use principally of the criteria named under 3 and 4, was the first to obtain an entirely satisfactory answer to the question. He has shown that in the central nervous system of "*Clepsine hollensis*" (which is closely related to *G. parasitica*) there are present thirty-four ganglia, each giving off paired nerves. Six of these ganglia are found in the anterior ganglionic mass which encircles the pharyngeal sac; seven are found in the posterior

ganglionic mass which lies in the posterior sucker and supplies it with nerves; these, added to the twenty-one distinct ganglia found in the central part of the body, bring the total up to thirty-four. An examination of the sense organs connected with these ganglia, and situated typically on the middle ring (first, Whitman) of each somite, yields corroborative evidence that the number of somites represented in the body is thirty-four.

Bristol ('99) subsequently made a similar study of the metamerism of *Nepheleis lateralis*, his conclusions being for the Gnathobdellidæ entirely in harmony with those of Whitman for the Rhynchobdellidæ.

Oka ('94), however, has cast doubt upon the general applicability of Whitman's determination, based as it was on the metamerism of a single species of *Glossiphonia*, by stating that in the several European species which he has studied (*G. stagnalis*, *G. complanata*, *G. concolor*, *G. heteroclita*, *G. papillosa*, *G. marginata*, and *G. tessellata*) he finds evidence of *only five* (not of six) fused ganglia in the brain. Moreover, in recent systematic papers, such as those of Blanchard ('94) and Moore ('99), we find the body of the leech still analyzed and described as consisting of twenty-six preanal somites, instead of twenty-seven, the number found in that portion of the body by Whitman ('92) and Bristol ('99), and still earlier, though on less satisfactory evidence, by Apáthy ('88).

Accordingly, I have thought it worth while to examine into this matter rather carefully in the case of the species studied by me.

I may say at once that my results, in the case of all six species studied, are in complete accord with those of Whitman ('92), so far as the *number* of metameres is concerned. In determining the *limits* of the somite, I have arrived at conclusions differing from those of my predecessors, as will presently appear (p. 31 ff.).

a. Structure of a Typical Ganglion. — A typical ganglion from the middle of the body has its ganglion cells arranged in six groups enclosed in capsules of connective tissue. Four of these capsules are lateral in position, two on each side of the ganglion; the other two occupy a mid ventral position, one in the anterior, the other in the posterior part of the ganglion. (See the ganglion of somite xxvi. in Figure 9, Plate 3.) Three nerves are given off close together from either side of the ganglion, and are distributed to the three successive rings of one and the same somite, as I have elsewhere (Castle, 1900) pointed out.

If, then, we can determine exactly how many such ganglia are present in the central nervous system of a leech, we shall be in a position to say how many somites enter into the composition of its body.

In the middle part of the body, as already stated, twenty-one distinct ganglia of the sort just described can easily be recognized. To determine how many are present toward either end of the body, where more or less fusion of ganglia has taken place, is a matter of more difficulty.

β. Fused Ganglia. — Figure 9 (Plate 3) shows a dorsal view of the posterior part of the central nervous system of *G. stagnalis*, obtained by reconstruction from a series of frontal sections. The last two distinct ganglia, those of

somites XXVI. and XXVII., are shown, followed by the nerve mass of the posterior sucker, made up of seven fused ganglia. In it seven pairs of lateral capsules appear on either side, a segmental nerve root being closely connected with each pair (XXVIII.-XXXIV.). The more posterior of the lateral capsules has in the case of each pair been displaced outward and downward (ventrad) and been reduced in size. The position of the seven pairs of ventral capsules is indicated by dotted outlines, the numeral denoting the somite to which each capsule belongs. In the first and last of the fused ganglia of this region, the ventral capsules occupy their typical tandem position (as in ganglion 26); in the case of the intervening ganglia (29-33), we find a more or less complete displacement of the ventral capsules to a side-by-side position. A similar displacement occurs in ganglion 27, which lies close back against the septum which divides the lacunar space of the posterior sucker from that in which the more anterior portions of the central nervous system lie. The same mechanical cause, crowding in an antero-posterior direction, explains both phenomena of displacement.

The evidence presented in Figure 9 leaves no room for doubt that seven primitive ganglia are found in the nerve mass of the posterior sucker in this species. Determination of the number of ganglia represented in the brain mass is not quite so easy, but the evidence is likewise convincing. The brain (*b.*, Figures 4, 7) forms a ring of nervous substance situated commonly in the last ring of somite VI. and the first two rings of somite VII. It surrounds the thin-walled pharyngeal sac (*sac. phy.*, Figure 1), there being in leeches no recognizable separation into supra- and sub-oesophageal ganglia.

A lateral view of the brain and the metameric nerves given off from it is shown in Figure 8; a view of its dorsal surface in Figure 12. Figure 10 shows the arrangement of the capsules on its ventral surface. An examination of Figures 8 and 10 shows that the capsules (6, 6) of the last brain ganglion have quite their typical arrangement. A triple segmental nerve (VI., Figure 8) emerges from under a pair of lateral capsules, while below a pair of ventral capsules are arranged in the usual tandem order (6, 6, Figures 8, 10).¹

Ganglia 3-5 likewise present no special difficulties, their lateral capsules being present in pairs with nerve roots attached (3, 3: 4, 4: 5, 5, Figure 8).

¹ I have been unable to determine to what extent in the reduced somites at the two ends of the body the original triple nature of the segmental nerves persists. The nerve of the last brain ganglion is certainly triple (VI., Figure 8), as we should expect from the fact that somite VI. consists of three distinct rings (Figures 4, 7). Most of the nerves anterior to this one, perhaps all, are either double or triple, but as I have been unable to determine accurately which condition exists in some of them, I represent the nerve as undivided in the case of the first five somites (Figure 8). For a like reason I follow a similar course in representing the segmental nerves of the posterior ganglionic mass (Figure 9). I think that all of these nerves are made up of at least two distinct bundles of fibres; whether the small third nerve is also present as a distinct element in any or all of them, I am unable at present to say.

Their ventral capsules show the following modification in arrangement; they have been displaced from the typical tandem position to a side-by-side position (Figures 8, 10; compare Figure 9, somites XXIX.-XXXIII.).

The lateral capsules of ganglion No. 2 are found dorsal to the pharyngeal sac (2, 2, Figures 8, 12). They seem to have been displaced backward to a position somewhat posterior to the lateral capsules of ganglion No. 3 by a migration in that direction of the supra-œsophageal commissure (Figure 8; compare Figures 11, 21). The commissure in this species is normally thrust back of the position in which it is shown in Figure 8, so that it lies about over the lateral capsules of ganglion No. 5. The animal whose brain is represented in Figure 8 was curved ventrad so that the commissure was thrust forward of its usual position and the row of lateral capsules below it was straightened out a little. The position of the ventral capsules of ganglion No. 2 is shown in Figures 8 and 10; the nerve root (II., Figure 8) arises at the anterior end of the brain just ventral to nerve root I.

The ganglionic capsules of neuromere No. 1 *all* lie dorsal to the pharyngeal sac and anterior to the supra-œsophageal commissure (Figures 8, 12). I believe that the most anterior and ventral of these (I v., Figures 8, 12), which lies closely attached to nerve root I. in each half of the body, is homologous with a ventral capsule of one of the succeeding ganglia. Capsule I v. extends out lateral to, sometimes even ventral to, nerve root I., so that its end may appear in sections between nerve roots I. and II.

Oka ('94) states that he finds in the brain of "Clepsine" (*Glossiphonia*) always *thirty* nerve capsules, and he accordingly regards it as equivalent to *five* fused ganglia and no more. Since *G. stagnalis* was one of the species studied by him, I am unable to understand how he can have reached such a conclusion, unless he has overlooked altogether the capsules of somite I. which lie *anterior* to the supra-œsophageal commissure.

Both the number and arrangement of the nerve capsules, and the number and position of the nerve roots, show clearly that in G. stagnalis SIX fused ganglia are represented in the brain, and that in the entire body THIRTY-FOUR somites are represented.

(2) Somite Limits.

It remains to explain the grounds on which the limits of the somites have been placed by me as indicated in Figure 4. Whitman ('85) pointed out many years ago that a certain ring (the first, according to his account) of each typical somite in the body of a leech is more richly supplied with sensory organs ("sensillæ") than any other ring of the somite. In many species of *Glossiphonia* special color markings or papillæ are also found on the sensory ring. Color markings, however, are wanting in *G. stagnalis*, and the sensillæ are not sufficiently conspicuous in the living animal to make identification of the sensory rings at all certain. But a carmine stain of the proper intensity renders identification of the sensory rings quite easy by giving them, especially along the margins of the body, a somewhat darker color. Observing this fact,

I was first enabled to determine as sensory the rings indicated by Arabic numerals in the right half of Figure 4; further study revealed the presence of marginal sensillæ in the positions indicated in Figure 3.

The metamerically repeated sensory annuli were thus positively identified throughout the greater part of the body. It remained merely to mark off the somite limits between successive sensory annuli. This I at first did after the usage of Whitman ('85, '92) and practically all others since the time of Gratiolet ('62), considering the sensory ring as occurring *at the anterior end of its somite*.

I found, however, that a consistent following of this practice would, toward either end of the body, place the somite limits *in the middle of a ring* instead of between rings, the position in which somite boundaries fall in other regions of the body. See Figure A, xxv', xxvi', etc.

FIGURE A. — *G. stagnalis*. Dorsal view of posterior part of body, showing marginal sensillæ. Somite limits are indicated correctly at the right of the figure (xxiv. to xxvii.); at the left of the figure (xxiii' to xxvii') they are shown as they have been commonly but incorrectly placed.

This led me to inquire whether the sensory ring really is the anterior ring of its somite. The results of this inquiry have been published elsewhere (Castle, 1900), so that only one or two of the more important conclusions need be restated here. One of these, already suggested in part on page 29, is the following: —

Somite limits coincide with neuromeric limits; consequently in Glossiphonia the sensory ring is the middle, not the anterior ring of the somite.

This point being established, the somite limits must be marked off, in the regions where unabbreviated somites occur, as in Figure 4, VI.-XXIV.

I have further shown, in the publication already cited, that in *Glossiphonia* somite abbreviation¹ is accomplished by a series of steps which follow one another in regular sequence. First, a union takes place between the sensory ring and the ring which precedes it; secondly, the ring which follows the sensory ring is reduced in size; finally, it too fuses with the sensory ring, the entire somite being then represented by a single external ring.

If, as is not improbable, some of the "abbreviated" somites are really in arrested stages of development from the one-ringed to the three-ringed condition (as suggested in the case of *Microbdella* by Moore, 1900), the order of the three steps enumerated should be reversed, in their case, and described in the following terms: (1) A distinct narrow ring is separated off at the posterior end of the uniannulate somite; (2) this newly formed posterior ring grows in width; (3) another new ring is separated off at the anterior end of the somite. This produces a three-ringed somite, all three rings ultimately attaining an equal width. For convenience in description, however, the process will be uniformly treated as one of abbreviation, as explained on page 22, footnote.

The amount of "abbreviation," as is well known, becomes greater toward either end of the body.

Bearing in mind these principles, we find that the least affected of the abbreviated somites of *G. stagnalis* are those which stand nearest to the unabbreviated somites, namely, v. (Figure 3) at the anterior end of the body, and xxv. (Figure 4) at the posterior end. In the case of each of these, the anterior and sensory rings of the somite are united into a single broad ring. But in the case of somite v. we find the union occasionally incomplete, as indicated by the notch (less clearly than it should be) at the upper margin of Figure 3, ring 4.

Somite xxvi. (Figure 4; Figure 34, Plate 8) is usually found in the same condition of abbreviation as the somites just described. Occasionally, however, its posterior ring is narrower or less distinct than that of somite xxv.

In somites iii. and iv. the process of abbreviation to a single broad ring is practically complete, although the narrow posterior ring is in favorable preparations still recognizable as a distinct element separated from the rest of the somite by a shallow transverse furrow (Figure 7, iii., iv.).

Somites i., ii., and xxvii. have each been reduced to a single ring; in addition a fusion (sometimes incomplete) has taken place between somites i. and ii., so that they are together represented by the broad ring, 1 (Figure 7).

Somites xxviii.-xxxiv. are not represented by annuli on the surface of the body; they form collectively the posterior sucker.

¹ As to the sense in which this term is used, see p. 22, footnote.

2. *Glossiphonia fusca* sp. nov.

Plate 4.

a. HABITAT, FORM, SIZE, COLOR.

This species is rather closely related structurally to *G. stagnalis*, with which I have found it associated in the vicinity of Cambridge, Mass., and Trenton, New Jersey. It is of about the same size as *G. stagnalis*, but is broader in proportion to its length (Figure 13, Plate 4). In its movements it is somewhat more sluggish than that species and does not stretch itself to so great a length.

Length of largest individuals, fully extended, 20 mm.; at rest, 9 mm.

Greatest width, when fully extended, 2.5 mm.; at rest, 4 mm.

Color, a coffee-brown above, somewhat lighter below. The general brown coloration is due to the presence in the superficial layers of the body of slender, branched, thread-like pigment cells bearing numerous knot-like swellings and filled with a dark-brown pigment. Such pigment cells are clearly homologous with the pigment cells found in a superficial position in the body of *G. stagnalis*, — Graf's "excretophores." They are much more abundant on the dorsal than on the ventral surface. On the former they appear in greatest numbers in a median dark band about as wide as two or three body rings; but they are entirely wanting anterior to the eyes and in the following regions, which therefore appear as clear, transparent areas: —

1. A transverse row of circular spots found on the sensory ring of each somite. These spots are about the width of a ring in diameter. Their maximum number is seven, but it is a rare occurrence to find all seven present in a single somite. Each spot occupies a definite position on its ring, so that those of successive somites form seven longitudinal rows, three in each half of the body and one median in position. The paired rows may be designated as *marginal*, *intermediate*, and *paramedian*, for they occupy positions which correspond closely with those of the rows of dorsal papillæ so designated in the case of *G. parasitica* (Plate 2, Figure 6).

The paramedian rows of clear spots are more constant in occurrence than any of the others; they can usually be found on somites v.-xxvi. The intermediate and marginal rows usually begin about in the region of the genital pores and continue with increasing distinctness back to the anus. The median row is less well developed than any of the others. It is represented by an occasional clear spot in the region posterior to the genital pores and anterior to somite xxii.

2. In the region of somites xxii.-xxvi., the median row of clear spots is suddenly replaced by a continuous clear band about as wide as one of the spots. Along the margins of this clear band, the pigment is unusually abundant, which fact adds by contrast to the conspicuousness of the median band.

3. The margin of the posterior sucker, where it projects beyond the outline of the body as seen in dorsal view, usually bears eight or ten triangular or

rounded clear spots of approximately the same form and position as the yellow pigment spots found on the posterior sucker of *G. parasitica* (see stippling in Figure 6).

4. The sensory ring of each of the somites in the neck region — somite v. and a few of the following — is occasionally distinguished by an uninterrupted, but narrow, clear band, which runs entirely across it from one side of the body to the other, occupying about its middle third.

The conspicuousness of the unpigmented areas just described, except that mentioned under (4), is increased by the presence in the centre of each of a group of peculiar reserve-food cells, which lie quite near the surface of the body.

The *ordinary reserve-food cells* of this species agree in practically every particular of structure and distribution with those of *G. stagnalis*. They are large rounded cells, sometimes attaining a diameter of eighty mikra or more. The granules within their cytoplasm attain a diameter of six or seven mikra. The color of these cells by reflected light is a pale orange; by transmitted light, they are semi-transparent, of a leaden gray color. They are distributed irregularly through the middle and posterior portions of the body, being situated in its deeper parts.

The *special form of reserve-food cell*, which is found in the segmental clear spots already described, differs in respect both to size and to color from the ordinary reserve-food cell. It is considerably smaller, — forty to fifty mikra being the maximum diameter observed, — and its contained granules are likewise smaller, though more numerous. Its color by reflected light is a bright lemon yellow; by transmitted light it is brown. Finally this variety of reserve-food cell is invariably situated quite near the surface of the body. The appearance of a group of these cells as seen under a moderately high power of the microscope is shown imperfectly in Figure 17 (Plate 4).

The ventral surface of the body is pigmented in very much the same fashion as the dorsal, but less heavily. There is, however, this difference in the distribution of the superficial brown pigment: on the ventral surface a pair of narrow, paramedian, pigmented lines can be recognized, one in each half of the body, in about the position of those found both dorsally and ventrally in *G. elegans* (Figure 30, Plate 7). On the dorsal surface, on the other hand, the most heavily pigmented region is a broad median band (p. 34).

Segmental clear spots are found on the sensory rings on the ventral surface also, and these are arranged in paramedian, intermediate, or marginal rows; but the spots are much less conspicuous than on the dorsal surface, and the lemon-yellow reserve-food cells are less often found in their centres.

Comparing the coloration of this species with that of *G. stagnalis*, we may say that the histological elements which produce the coloration are very similar in the two, but the distribution of these elements is such as to produce in *G. fusca* a distinct color pattern (longitudinal striations and segmental clear spots), a feature entirely wanting in *G. stagnalis*.

b. RINGS, SOMITES, EYES, SUCKERS.

External rings, not quite so distinct as in *G. stagnalis*; skin, slightly rougher owing to the stronger development of Bayer's ('96) sense organs. Number of preanal rings, seventy (Figure 13, Plate 4).

Somites v.-xxiv. are triannulate, but the two anterior rings of v. are united ventrally (Figure 15).

Somites i. and ii. are included in a single broad ring, which, just as in *G. stagnalis*, is sometimes subdivided by a shallow transverse furrow (Figure 14) marking the boundary between the two incompletely fused somites.

Somites iii., iv., xxv. and xxvi. (Figures 13-16) are biannulate. In each case the broader, anterior ring bears the sensillæ and corresponds to rings 1 and 2 of triannulate somites (compare somites iv. and v. of Figure 15).

Somite xxvii. is a single broad ring (70, Figure 13) which lies just anterior to the anus, not crowded back of it, as in *stagnalis* (Figure 34, Plate 8).

The principal differences in somite composition between *fusca* and *stagnalis* occur in the head region, in somites iii.-v. These somites are less abbreviated (or more fully elaborated) in *fusca* than in *stagnalis*, hence the greater number of preanal rings in the former (seventy) as compared with the latter (sixty-seven).

Eyes, two, large and distinct, situated in rings 3 and 4 (Figures 14-16). The sensory elements of each eye, as in *G. stagnalis*, are contained in a pigment cup which is open only on its anterior, lateral surface, where the nerve fibres make their exit (Figures 14, 16).

Oral sucker, as in all species of *Glossiphonia*, included within the first four somites (Figures 14, 15).

Posterior sucker of about the same dimensions as in *G. stagnalis*, slightly longer than broad.

c. REPRODUCTIVE ORGANS.

Male genital pore (po. ♂, Figure 13), between the first and second rings of somite xii. (rings 27 and 28).

Female genital pore (po. ♀, Figure 13), between the second and third rings of somite xii. (rings 28 and 29).

Testes (te., Figure 13), six pairs situated intersegmentally in somites

xiii.	xviii.
xiv.	xix.

The *ovaries* have the usual form and position of these structures in other species, being found ventrally in the median lacuna.

Eggs are laid a month or six weeks later than by *G. stagnalis* (June 12, 1898, Cambridge, Mass.). In color they resemble those of *G. stagnalis* closely, being of a light pink or flesh color. As in *G. stagnalis*, the eggs are attached to the under side of the body posterior to the genital pores, within a number of delicate sacs arranged in two parallel rows, close together, one on each side of the median plane. The number of sacs is most often six, but a seventh sac

was observed in one case. The number of eggs in a sac, as well as the total number of eggs laid by an individual, is greater in this species than in *G. stagnalis*. The following figures will indicate the number of eggs borne by four good-sized individuals, which laid eggs in the laboratory in June, 1898. The vertical line represents the median plane of the body; the positions of the numerals show how the sacs were placed with reference to one another and to the median plane of the body; the numerals themselves indicate how many eggs were in each sac. Anterior is toward the top of the page, and the right side of the body toward the left of the page, the animals having been observed in ventral view.

INDIVIDUAL I.

<i>a.</i>		
	$\frac{16}{22} \mid \frac{17}{13}$	
<i>r.</i>	$\frac{16}{22} \mid \frac{20}{13}$	<i>l.</i>
<i>p.</i>		

Total $54 + 50 = 104$

INDIVIDUAL II.

<i>a.</i>		
	$\frac{11}{18} \mid \frac{6}{14}$	
<i>r.</i>	$\frac{11}{18} \mid \frac{13}{14}$	<i>l.</i>
<i>p.</i>		

$44 + 33 = 77$

INDIVIDUAL III.

<i>a.</i>		
	$\frac{2}{19} \mid \frac{13}{18}$	
<i>r.</i>	$\frac{18}{19} \mid \frac{20}{18}$	<i>l.</i>
<i>p.</i>		

$39 + 51 = 90$

INDIVIDUAL IV.

<i>a.</i>		
	$\frac{16}{17} \mid \frac{5}{13}$	
<i>r.</i>	$\frac{21}{17} \mid \frac{19}{13}$	<i>l.</i>
<i>p.</i>		

$54 + 51 = 105$

Average number of eggs in a sac in above cases, 15 (as against 4 in *G. stagnalis*); average number of eggs borne by an individual, 94 (as against about 30 in the case of *G. stagnalis*).

It will be noticed that one of the anterior sacs often contains a relatively small number of eggs (as noticed in the case of *G. stagnalis* also), suggesting that it served to finish off the egg-laying, the sacs being arranged in the order in which they were formed, from behind forward.

d. DIGESTIVE TRACT.

The *mouth* is situated anterior to the eyes, well forward in the anterior half of the oral sucker (Figures 14, 15). From here the thin-walled *pharyngeal sac* (*sac. phy.*, Figure 13) leads back to the base of the proboscis in somite XII., just behind the male genital pore. When the animal is at rest the *proboscis* (*pr'b.*, Figure 13) usually extends through the four somites between the brain and

the male genital pore (VIII.-XI.) into somite XII., where it receives the ducts of the salivary glands, a bundle from either side of the body.

The *salivary glands* themselves are very large in this species and are distributed in the marginal part of the body through somites XI.-XVII., or, in exceptional cases, even a somite farther in one direction or the other.¹

The short *œsophagus* (*œ.*, Figure 13) extends from the base of the proboscis through somite XIII. to the beginning of the crop in somite XIV.

The *crop* (*i'glv.*, Figure 13) extends over the six somites XIV.-XIX., giving off in the middle of each a pair of conspicuous lateral diverticula. *These are always evident whether the crop contains food or not*, a condition very different from that which exists in *G. stagnalis*. The last pair of crop diverticula (those of somite XIX.) are very long but simple, as in *G. stagnalis*, without secondary lateral diverticula. They extend back over the entire stomach region, usually ending in somite XXIII.

The *stomach* (*ga.*, Figure 13), which is separated from the crop by a valve-like constriction, bears four pairs of lateral diverticula doubtless originally metameric in arrangement, but now arising within the limits of somites XX.-XXII.

The *intestine* (*in.*, Figure 13) leads from the stomach back to the anus, which is situated dorsally just behind somite XXVII., as in other species of *Glossiphonia*. The intestine includes anteriorly two rather spacious chambers, the first of which bears a pair of small ear-like diverticula from its anterior lateral borders. Behind these chambers comes a simple tubular part terminating at the anus.

To sum up, *the particulars in which the digestive tract of G. fusca differs conspicuously from that of G. stagnalis* are (1) the shorter proboscis and larger *œsophagus*; (2) the larger salivary glands, distributed through a greater number of somites; (3) the persistent character of the first five pairs of crop diverticula; (4) the distinctly chambered condition of the intestine, and the pair of diverticula borne by its first chamber.

Nephropores are found on the sensory ring of each of the somites VIII.-XXIV., with the possible exception of XIII., where, as in *stagnalis*, the nephridia are much reduced, if not wholly wanting, — a fact accounted for by the strong development of the salivary glands and genital ducts in that region. The nephropore lies usually a little anterior to the middle of the ring on which it is found.

e. NERVOUS SYSTEM.

A ventral view of the brain is shown in Figure 18, a dorsal view of that part of it which lies above the pharyngeal sac is shown in Figure 16, the position of the ventral part being indicated by a dotted line; the outline of the brain

¹ The animal shown in Figure 13 was a small one, and the salivary-gland cells are proportionally a little larger than they would be in the average, full-grown animal.

as seen in a lateral view is shown in Figure 14, *cb*. It lies for the most part in somites VII. and VIII. This is about a somite posterior to the usual position of the brain in *G. stagnalis* (Figures 4, 7).

The number of fused ganglia represented in the brain is, as in *G. stagnalis*, six, and the nerve capsules have the same general arrangement as in that species. The ventral capsules of neuromeres II.-V. are placed side by side, while those of neuromere VI. lie one behind the other (Figure 18; compare Figure 10, Plate 3). The six capsules of neuromere I. are situated well dorsal, as in *G. stagnalis*, and the supra-œsophageal connective is pushed back nearly over the middle of the entire brain mass (Figures 14, 16). The lateral capsules of neuromere II. are shown in the dorsal view (Figure 16); those of neuromeres III.-VI., in the ventral view (Figure 18).

In Figure 14, which represents a parasagittal section, is shown the position of the paramedian sensillæ of the head somites, certain of which also appear in Figure 15. These indicate clearly the sensory rings of the somites in that region, and so aid in the determination of the external limits of the somites. The eye is clearly derived from one of the segmental organs of somite III. (ring 2), as the position of its nerve indicates. This view is confirmed by a comparison with the conditions existing in *G. heteroclita* and *G. elegans*.

3. *Glossiphonia elongata* sp. nov.

Plate 6.

a. HABITAT, FORM, SIZE, COLOR.

This leech first came to my notice in September, 1898. While collecting *G. stagnalis* from Spy Pond, near Cambridge, I found three or four leeches which, although of about the same size as *stagnalis* and occurring in similar situations, at once attracted my attention because of their more slender bodies and the peculiarities of their movements. These animals were carefully preserved, and diligent search was made the following spring for more. This search, however, was fruitless; but in September, 1899, I was fortunate enough to find quite a number of individuals in a pool near Fresh Pond, Cambridge, some of which I have since kept alive in aquaria for several months.

The body is less flattened dorso-ventrally in this species than in any other *Glossiphonia* known to me, being sub-cylindrical in cross-section. It is extremely slender, even when contracted, and both head and acetabulum are small (Figure 27, Plate 6). This species does not roll itself into a ball, as other species do, when disturbed. Instead, it writhes about or twists itself into knots like an earthworm. In aquaria it moves little from place to place, but, attached by its weak posterior sucker, extends its snake-like body searching hither and thither as for a place of concealment, or, losing its attachment, seems unable to regain it and writhes helplessly like an earthworm on a smooth surface.

The largest individuals which I have examined measure as follows:—

Length, fully extended, 25 mm. ; partially contracted (as in Figure 27), about 10 mm.

Width, fully extended, less than 1 mm. ; partially contracted (as in Figure 27), about 1.5 mm.

Color.—The anterior and marginal parts of the body are very clear and transparent. The rest of the body is usually of a pale yellowish-white color when the animals are first collected, but changes to a rusty yellow or pale orange color if they are kept in well-lighted aquaria for a few days. The color is due to the presence in the deeper parts of the body of rounded reserve-food cells, similar to those described as occurring in *G. stagnalis*. Apparently the nature of the granules in the reserve-food cells changes under the influence of daylight, so that by reflected light they appear pale orange instead of yellowish-white, the color which they have when first collected.

Superficial pigment cells of the branched type, described as occurring in *G. stagnalis* and other species, appear to be entirely wanting in *G. elongata*.

Fat cells occur in abundance in the deeper parts of the body, the contained oil drops being perfectly clear and transparent, as in *G. stagnalis* and *G. fusca*.

b. RINGS, SOMITES, EYES, SUCKERS.

The *skin* is very smooth and entirely free from papillæ.

External rings, broad and smooth, usually indistinct in the head region (somites I.–IV., Figure 23). Number of rings, 62 between oral sucker and anus (somites V.–XXVII.).

Notwithstanding the indistinctness of the rings in the head region, favorable preparations, like that represented in Figure B, show that the composition of somites I.–IV. is practically the same in this species as in *G. heteroclitæ* (Plate 5) and *G. fusca* (Plate 4). Somites I. and II. are uniannulate; somites III. and IV. biannulate, the anterior rings being broader and corresponding to rings 1 and 2 of a typical somite taken together.

Somite V. is likewise biannulate in this species, just as in *G. stagnalis* (Figure B; compare Plate 1, Figure 3); in all the other species with which this paper deals, somite V. is triannulate.

Somites VI.–XXIV. (Figure 27) are triannulate, as in all other known species of this genus. Somites XXV.–XXVII. are reduced each to a single ring, a condition found in the other species described only in the case of somite XXVII., somite XXV. being always biannulate, and somite XXVI. usually so.

Eyes, two, situated about as in *G. stagnalis*, just posterior to the mouth, between somites III. and IV. (Figure 23). The eyes are separated from each other by a considerable space, as in *G. stagnalis* (Plate 2, Figure 4) and *G. fusca* (Plate 4, Figure 16). The pigment associated with them is usually small in amount; often it is wanting altogether.

The *oral sucker*, as in the other species described, lies within the limits of somites I.–IV. The *mouth* lies about in its centre (Figure 23, Plate 6; Figure B). The *posterior sucker* (act., Figures 24, 27) is extremely small and weak. In

position it may be described as terminal rather than ventral (the position which it occupies in other species).

c. REPRODUCTIVE ORGANS.

The *genital pores* have the same position as in *G. stagnalis* and *G. fusca*; the male (*po.* ♂, Figure 27), between the first and second rings of somite XII., the female (*po.* ♀, Figure 27), between the second and third rings of the same somite.

FIGURE B.—*G. elongata*. Ventral view of head end, showing annulation of head somites and position of marginal sensillæ.

Testes (*te.*, Figure 27), six pairs placed intersegmentally in somites $\frac{\text{XIII.} - \text{XVIII.}}{\text{XIV.} - \text{XIX.}}$, as regularly in the genus.

The *ovaries* (*oa.*, Figure 27) have the typical structure and position which they possess in other species (see p. 25). The eggs and egg-laying of this species I have not observed.

d. DIGESTIVE TRACT.

The *mouth* (*or.*, Figure 23, Figure B) opens about in the middle of the oral sucker. The *proboscis* (*pr'b.*, Figure 27) commonly extends over about four somites (VIII.–XI.). The *salivary glands* (*gl. sal.*) are found chiefly in somite XII., though a few may lie in the adjacent somites, XI. and XIII. About thirty good-sized gland cells are found in either half of the body. In size, number, and position the salivary glands of this species resemble those of *G.*

stagnalis more closely than those of any other species (compare Figures 1 and 27).

The *crop* (*i'glv.*, Figure 27), as in *G. stagnalis*, bears a single pair of diverticula, which arise in the middle of somite XIX.; but the diverticula are shorter in this species than in *stagnalis*, ending usually in somite XX. (compare Figures 1 and 27). The *stomach* (*ga.*), as in all species of *Glossiphonia*, bears four pairs of lateral diverticula. They arise within the three somites XX.-XXII. All are directed slightly forward. The *intestine* (*in.*) is a simple tube not constricted into distinct chambers proximally as in most species. The *anus* (*an.*, Figure 24) lies just behind somite XXVII.

In the structure of its digestive tract, as well as in the composition of its somites, this species shows a more reduced, simpler condition than is found in any other species known to me, *stagnalis* coming nearest to it in these particulars.

e. NERVOUS SYSTEM.

On account of the transparency of the body the central nervous system can be studied with ease in this species, either in the living animal or in whole preparations. In the ventral ganglionic chain there are, as in all species of *Glossiphonia*, twenty-one distinct ganglia. These innervate somites VII.-XXVII. respectively.

The brain (*cb.*, Figures 23, 27; also Figures 25, 26) represents the fused ganglia of the first six somites. The arrangement of its ganglionic capsules is the same as in *G. stagnalis* and *G. fusca* (Figures 8, 10, 12, 18). The two ventral capsules of somite VI. (6, 6, Figure 25) are arranged tandem, those of somites I.-V., side by side. The supra-œsophageal commissure lies well back, about over the lateral capsules of somite V. (Figure 26).

4. *Glossiphonia heteroclita* LINNÆUS (1761).

Plate 5; Plate 8, Figs. 35, 36, 38.

Hirudo heteroclita Linnæus (1761); *H. hyalina* O. F. Müller (1774); *Clepsine hyalina* Moquin-Tandon ('26).

a. HABITAT, FORM, SIZE, COLOR.

This small and transparent leech is found both in Europe and in North America. Compared with *G. stagnalis* and *G. fusca*, it has a proportionally shorter and broader body (Plate 5, Figures 19, 22; Plate 8, Figure 38. Compare Plate 1, Figure 1; Plate 2, Figure 4); in its movements, it is less active. It is found in ponds and sluggish streams, such as *G. stagnalis* frequents.

Length of largest individuals, when extended, 13 mm.; at rest, 8-9.5 mm.

Width, extended, 3 mm.; at rest, 4.25 mm.

Color. — The body is in general very clear and transparent, like that of a jelly-fish, but shows great individual variation in the matter of pigmentation.

First, it always has more or less of a golden-yellow tint caused by the pres-

ence, in the deeper parts of the body, of large, rounded cells each containing a single yellow oil-drop, which is blackened when treated with osmic acid.¹

Secondly, there are usually present (but this is the variable element in the pigmentation) irregularly rounded, oval, or even somewhat branched cells, which contain pigment granules either orange, dark-brown, or black in color. These cells are found near the dorsal surface of the animal, and often produce a conspicuous color pattern by their abundance in certain regions (Figure 38, Plate 8). In their finer structure, cells of this variety are rather closely related to the deep-seated pigment cells (reserve-food cells) found in *G. stagnalis* and *G. fusca*; but in respect to position (close to the surface), and occasionally in form (irregular or branched), they approach more nearly the superficial pigment cells ("excretophores," Graf) of the species named.

The pigmented areas which are often produced in *G. heteroclita* by the superficial pigment cells just described are (Figure 38, Plate 8), first, a median dorsal, longitudinal band, which, when best developed, extends, with occasional interruptions, from about the seventh somite back to the anus. In the anterior ring of each somite it often broadens out into a trapezoidal form. Secondly, in about the same regions of the body (seventh to twenty-seventh somites), the anterior ring of each somite may be marked by a transverse, pigmented line, most conspicuous a short distance from the margin of the body, from which point it extends inward toward the trapezoidal, broad part of the median vitta, but rarely joins it.

Apáthy ('88) has recognized as a distinct variety (*striata*) animals which have the transverse markings just described. It must be said, however, that one can find in a lot of animals collected from the same locality all gradations between forms with no pigment at all (of the superficial sort) and those having a median vitta and well-defined transverse striations.

b. RINGS, SOMITES, EYES, SUCKERS, ETC.

The *surface* of the body is rather smooth, being only slightly rougher than that of *G. stagnalis*.

External rings, rather inconspicuous, particularly in the head region, where it is often difficult to determine their number and limits accurately.

Number of preanal rings, seventy, counting as a single ring each of the somites I., II., XXVI., and XXVII., Figure 19. This number may be increased, if one counts subdivisions occasionally visible in some of the rings at the ends of the body.

Somites I. and II., as just indicated, are commonly uniannulate (Figures 35, 36, Plate 8); but somite II. is sometimes subdivided by a transverse furrow (as shown in Figure 20, Plate 5).

¹ Fat cells are also found in the deep parts of the body of *G. stagnalis*, *G. fusca*, and *G. elongata*, but the contained oil-drops are in those species perfectly clear and transparent, so that they do not have the effect of pigment cells, as do the fat cells of *G. heteroclita*.

Somite III., within the anterior part of which lies the mouth (*or.*, Figure 20), is ordinarily biannulate, as are also somites IV. and XXV. (Figures 19, 35, 36). But in the section shown in Figure 20, ring 3, the anterior annulus of somite III., appears conspicuously subdivided, a rather unusual condition. On account of the obliquity of the section, the first three somites appear in that figure a little too long in proportion to their vertical dimensions. The sensilla shown in the anterior portion of ring 3 in Figure 20 is probably not one of the segmental sense-organs, for it is found on the wrong half of ring 3.

Somites V.-XXIV. are triannulate, as in *G. fusca*.

Somites XXVI. and XXVII. (reckoned as uniannulate) usually appear divided at the margin only into a broader anterior and a narrower posterior part.

Compared with the species already described, the somite composition of *G. heteroclita* is about the same as that of *G. fusca*, somite abbreviation being less extensive in these species than in *stagnalis* and *elongata*.

Eyes, usually six, the anterior pair small and generally, though not always, close together in ring 5 (Figures 35, 36, Plate 8). Sometimes this pair of eyes lies in ring 6; occasionally the pigment of one or both eyes is wanting altogether.

The second and third pairs of eyes are most often found in rings 7 and 8 respectively, but one pair or the other or both may lie a little anterior or a little posterior to the ordinary position (compare Figures 35 and 36).

The first and second pairs of eyes are directed forward and toward the side; the third pair is directed backward and toward the side (Figures 20, Plate 5; Figures 35, 36, Plate 8). The eyes in this species seem to belong to somites III., IV., and V., respectively (Figure 20); but it is possible (though I think hardly probable) that a more careful study of the nerve connections would show that in this species, as in *G. elegans* (Figure 29, Plate 7), they have been derived from the sensillæ of somites II.-IV. If so, the eyes have undergone a farther displacement backward in this species than in the case of *G. elegans* (compare Figures 20 and 29).

Oral sucker, formed by somites I.-IV. (Figure 20).

Mouth (*or.*, Figure 20), in the anterior part of somite III., usually a little anterior to the first pair of eyes.

Posterior sucker, as in other species, slightly longer than broad (Figure 19).

c. REPRODUCTIVE ORGANS.

Male and female genital ducts open between the first and second rings of somite XII. (rings 28 and 29, Figure 19) by a common pore, a condition peculiar, I believe, to this species.

Blanchard ('94) is certainly in error in describing the position of the genital pores as follows: "Porus genitalis masculus inter annulos 25-26, vulva inter annulos 27-28 hians."

Testes (*te.*, Figure 19), six pairs placed intersegmentally in somites $\frac{\text{XIII.}}{\text{XIV.}} - \frac{\text{XVIII.}}{\text{XIX.}}$. The terminal part of the vas deferens (ejaculatory part) is un-

usually stout and thick in this species and runs forward to the middle ring of somite XI. before turning sharply backward toward the genital pore (compare Figure 19 with Figures 4, 13, 27, and 28).

The *eggs*, which in the vicinity of Cambridge are laid in May or June (at about the time *G. fusca* is laying), are whitish in color and are attached *singly*, not in groups as in the other species described, to the under side of the body (Figure 22). The eggs are of about the same size as those of *G. stagnalis*. The number laid varies greatly with the size of the individual, the observed extremes being eleven and sixty-five. Figure 22 shows in ventral view a large individual bearing forty-five eggs, each enclosed in a separate delicate sac which serves to attach it to the under side of the body.

d. DIGESTIVE TRACT.

The *mouth* has the position most common in the genus, in the anterior part of somite III. (Figure 20).

The *proboscis* (*pr'b.*, Figure 19) is long and the *œsophagus* correspondingly short. The former ordinarily extends over somites IX.-XII. and part of XIII., and the latter ends in the anterior part of somite XIV., where the crop commences.

The *salivary glands* (*gl. sal.*, Figure 19) are large and distributed often through as many as seven or eight somites, usually somites XI.-XVII.

The *crop* (*i'glv.*, Figure 19) bears six pairs of strongly developed lateral diverticula, a pair arising in the middle of each of the somites XIV.-XIX. Some or all of the first five pairs may be bilobed distally, and each of the sixth pair, which are very long, and extend back into somite XXIII., bears about five secondary, lateral diverticula, which come off metamerically in somites XIX.-XXIII.

The *stomach* (*ga.*, Figure 19), with its four pairs of lateral diverticula, lies within somites XIX.-XXII.

The *intestine* (*in.*, Figure 19) begins about in somite XXII. and extends back to the anus just behind somite XXVII. Proximally it consists of one or two chambers limited by valve-like constrictions. Posterior to this it gradually narrows backward.

e. NERVOUS SYSTEM.

The brain (*cb.*, Figure 19) lies about in the eighth somite. The arrangement of its ganglionic capsules is peculiar in one respect. The ventral capsules of the last brain neuromere (Figure 21) lie side by side, not tandem as in the other species described in this paper. In other respects the arrangement of capsules is the same as that found in *G. stagnalis* and *G. fusca* (Figures 8, 12, 16, 18). In the individual whose brain is represented in Figure 21, the most ventral and posterior capsule of neuromere I. had a horn-like process extending back laterally into contact with the lateral capsules of neuromere III.; this condition, however, appears to be unusual.

5. *Glossiphonia elegans* VERRILL (1872).

Plate 7; Plate 2, Fig. 5; Plate 3, Fig. 11.

Clepsine elegans Verrill ('72); (?) *C. pallida* Verrill ('72); *C. patelliformis* Nicholson ('73).

a. HABITAT, SIZE, COLOR.

This species is very closely related to the European *G. complanata* L. and *G. concolor* Apáthy. Blanchard ('94), indeed, considers it identical with *G. complanata* L. and regards *G. concolor* Apáthy as merely a variety of the same species. However, both Apáthy ('88) and Oka ('94) testify to the perfect distinctness of *G. complanata* and *G. concolor*, which occur together in Europe. I have myself compared animals of the species to be described with alcoholic specimens of *G. complanata* from Zürich, Switzerland, and find certain small but constant differences between the two. I shall therefore describe the animals which I find here in the vicinity of Cambridge under the name proposed by Verrill in 1872, recognizing, however, that they are very closely related to the two European species (or varieties) named.

G. elegans (Plate 7) is found in localities similar to those frequented by *G. stagnalis*, often in company with that species. It is considerably larger, being much broader and thicker in proportion to its length, though scarcely longer.

In its movements it is more sluggish, resembling closely the small *G. heteroclita* in that regard. It adheres to the side of the aquarium with a tenacity displayed by no other of our species except *G. parasitica*.

The form of the body at rest is elliptical.

The largest individuals which I have collected measure, when alive, as follows:—

Length, fully extended, 28 mm.; at rest, 14–18 mm.

Width, fully extended, 5 mm.; at rest, about 7 mm.

Color.—Small individuals are usually of a bright, transparent green color. Adult animals, viewed with the naked eye or through a hand lens, appear of a reddish or greenish brown color, and are darker above than below.

The head is colorless. The dorsal surface of the body is marked with numerous small circular white spots, about the width of a body-ring in diameter. These spots are so placed as to form transverse and longitudinal rows, just as do the similar spots of *G. fusca*. The transverse rows fall on the sensory (middle) rings of their respective somites, each row containing seven spots, when the full number is present. Each of these seven spots falls in a different longitudinal row, there being three pairs of rows arranged symmetrically with reference to an unpaired (median) row, exactly as in *G. fusca*. The paired rows may be designated respectively *paramedian*, *intermediate*, and *marginal*, for they occupy practically the same position on the body as do the rows of white spots in the case of *G. fusca*, and the rows of papillæ in that of *G. parasitica* (Figure 6).

In addition to the spots which fall into rows as just described, a few spots are usually found scattered more or less irregularly over the surface of the body.

Two interrupted brown lines (Figure 30) appear in a paramedian position on the dorsal surface, the interruptions being due to the segmentally arranged white spots of the paramedian rows. A pair of similar, though fainter, dark lines is found on the ventral surface; but they are farther apart, including between them about the middle third of the ventral surface. The dorsal paramedian lines include between them (in the middle of the body) about one fourth of the width of the dorsal surface, which part is usually rather more heavily pigmented than the more lateral portions.

A median, clear, unpigmented band extends the entire length of the body on the ventral surface. The median row of light spots on the dorsal surface often run together in the posterior third of the body, forming a continuous light vitta.

Examining more minutely into the coloration of the animal, one finds that it is due to the same two classes of cells as produce the coloration of most other species: first, pigment cells proper, — "excretophores," Graf; and secondly, reserve-food cells.

The pigment cells proper, as in other species, occupy a superficial position in, or immediately underneath, the epidermis. They are stellate or richly branched, and are more abundant on the dorsal than on the ventral surface; in small individuals they are almost entirely wanting. The pigment in immature animals is a rust-colored or dull reddish-brown, but in full-sized animals it is usually dark-brown.

There is no pigment anterior and lateral to the eyes, nor in the white spots already mentioned. The pigment is more abundant than elsewhere in the paramedian dark lines, indeed its abundance there *produces* those lines.

The reserve-food cells in this species, as in *G. fusca*, are of two forms: first, the ordinary form of large reserve-food cell distributed irregularly through the deeper parts of the body; secondly, a special form of reserve-food cell, smaller, and more superficial in position, and found only in the white spots already described.

The *ordinary reserve-food cells* are large and rounded in outline, often attaining a diameter of forty mikra or more. They contain rounded granules of a bright green color both by reflected and by transmitted light. It is this form of cell which gives to the small, immature individuals their green color, and often imparts a greenish tone to the brown-colored adults.

The *special form of reserve-food cell* agrees closely both in appearance and in distribution with the similarly designated structures of *G. fusca*. It is found, as already stated, only in the white spots of the dorsal surface; cells of this kind occur in a group of from two to a dozen or more each, situated in the centre of a white spot, just underneath the epidermis. By reflected light they are of a light lemon-yellow color; by transmitted light, greenish-brown.

Each of the white spots in the paired rows contains an inconspicuous, low rounded papilla (much less prominent than are the papillæ of *G. complanata*, so far as my observations go).

The median row of white spots is less well developed than are the paired rows; in the four or five somites immediately anterior to the anus, it is commonly replaced by a continuous, median, clear vitta, within which is seen a narrower band of the lemon-yellow reserve-food cells.

Obviously the color pattern of this species resembles very closely that of G. fusca, although in a majority of characters the animal is more closely related to G. parasitica.

b. SURFACE, RINGS, SOMITES, EYES, SUCKERS.

The *surface* of the body is rather rough, owing to the strong development in this species of the integumental sense-organs described by Bayer ('98). It does not, however, bear conspicuous papillæ, as is the case with *G. parasitica* and the European *G. complanata*. The low, rounded papillæ which are found in the paired longitudinal rows of white spots are much smaller than the similarly placed papillæ of *G. complanata*. In this particular *G. elegans* seems to agree with *G. concolor* (see Apáthy, '88, page 771).

External rings, as a rule, rounded and distinct, *less convex and not pointed as are those of G. complanata*, sixty-eight in number, distributed as follows:—

Somites I.-IV. uniannulate; but the boundary between rings 1 and 2 is often inconspicuous (compare Figures 28, 29, 30), approaching the condition found in *G. stagnalis*, where somites I. and II. form a single broad ring, which, however, is sometimes divided by a shallow transverse furrow (Figures 3, 7).

Somites V.-XXIV. triannulate, but the condition of somite V. is peculiar. Its anterior annulus (5, Plate 7, Figures 28-31) is commonly narrow and imperfectly separated from the following (sensory) annulus (6). This case illustrates well the initial step in reduction (or final step in elaboration, p. 33) of the triannulate somite. It represents an intermediate stage between the biannulate and triannulate condition of somite V. seen respectively in *G. stagnalis* (Figure 7, Plate 3) and *G. heteroclita* (Figure 20, Plate 5).

Somite XXV. is biannulate (Figure 28), but the furrow between its two annuli is often inconspicuous. Somites XXVI. and XXVII. are commonly uniannulate, though notched at the margin of the body, which fact shows that the final step in somite reduction (or initial step in somite growth) is not yet accomplished in the case of these somites.

Eyes, six, in two parallel rows close together, in rings 3 and 4 (Figure 30). Sometimes the first pair of eyes lies partly in the posterior half of ring 2 (Figure 29). The middle pair is the largest of the three; the anterior pair, the smallest. The first two pairs are directed obliquely forward, the last pair obliquely backward; all are turned away from the median plane (Figures 29, 30). From the relation of the eyes to the nerves connected with the metameric sensillæ (Figure 29), it is plain that the three pairs of eyes have been derived from the sensillæ of somites II., III., and IV. respectively. It is further evi-

dent that the single pair of eyes found in each of the species *stagnalis*, *fusca*, and *elongata* corresponds with the middle (largest) pair of eyes of this species, the pair belonging to somite III.

The *oral sucker*, as in the other species described, lies within somites I.-IV. (Figures 29, 31).

c. REPRODUCTIVE ORGANS.

Male genital pore (po. ♂, Figure 28), between somites XI. and XII. (rings 25 and 26), a position one ring anterior to that of the same structure in the species already described.

Female genital pore (po. ♀, Figure 28), between the second and third rings of somite XII. (rings 27 and 28), the usual position of this structure in the genus.

Testes (te., Figure 28), ten pairs. The anterior six pairs occupy the same positions as the testes in the species already described, being placed intersegmentally in somites $\frac{XIII.}{XIV.} - \frac{XVIII.}{XIX.}$. The remaining four pairs occur immediately

behind those already mentioned; the most anterior one, between the last crop and first stomach diverticulum, in somites $\frac{XIX.}{XX.}$; the other three between

successive stomach diverticula, and like them separated by rather less than metameric intervals. No other species of *Glossiphonia* known to me, except the European *G. complanata*, has normally a greater number of testes than six pairs. In that species likewise the testes number ten pairs placed exactly as in *elegans*. This is one of several facts showing the very close relationship of the two species named. The last one or two pairs of testes are less constant in their occurrence than those farther forward.

Eggs are laid by *G. elegans*, in the vicinity of Cambridge, in April, May, or as late as June. The temperature of the water in the spring undoubtedly exercises considerable influence in determining the time of egg-laying. Individuals brought into the laboratory on March 27, 1898, laid eggs nine days later. On April 29, 1900, animals of this species bearing eggs were collected from Alewife Brook, Cambridge, though *G. stagnalis*, found with them, apparently had not yet laid its eggs. The eggs are dull pinkish white in color and are borne on the under side of the body in from three to six large clusters, which are rather easily detached from the body, if the animal is disturbed. Each cluster contains a considerable number of eggs, often as many as twenty or twenty-five, enclosed in a delicate sac. The sacs are not arranged symmetrically in two parallel rows, as in *G. stagnalis* and *G. fusca*, but quite irregularly, a sac being attached either in the median plane of the body or to one side of it, as the case may be.

d. DIGESTIVE TRACT.

The *mouth* is situated well forward in somite III., anterior to the eyes, or at least anterior to the last two pairs of eyes (Figures 29, 31).

The *proboscis* (*pr'b.*, Figure 28) is long, extending over somites VIII.-XII. There is practically no œsophagus, as I have used the term, for the pharyngeal sac containing the proboscis extends back almost to the beginning of the crop.

The *salivary glands* are numerous, often reaching seventy-five or more in number in each half of the body. They are scattered usually through somites XI.-XVIII. In Figure 28 they are represented as relatively a little too small.

The *crop* (*v'glv.*) bears *seven* pairs of large, lateral diverticula directed backward and often lobed distally. They arise in somites XIII.-XIX., always in the middle of a somite, as in the other species described. The last pair of crop diverticula is, as usual, the largest of all; it may extend back through three or four somites, giving off secondary lateral diverticula metamerically, as shown in Figure 28. Often, however, when the crop is empty, the last pair of diverticula is little longer than the preceding pair.

The *stomach* (*ga.*, Figure 28) bears, as in other species, four pairs of diverticula, which arise within the three somites XIX.-XXI. The *intestine* (*in.*) extends through the six remaining somites, consisting proximally of two distinct chambers limited by valve-like constrictions and usually situated in somites XXII. and XXIII. Distally it is a gradually narrowing tube terminating at the anus just behind somite XXVII.

e. NEPHROPORES, NERVOUS SYSTEM.

The *nephropores* open ventro-laterally, a little anterior to the middle of the sensory ring of a somite. The number of nephridia has not been determined for this species.

The *brain* (*cb.*, Figures 28, 30) lies for the most part in somite VII. The arrangement of its ganglionic capsules (Figure 5, Plate 2; Figure 11, Plate 3) is usually similar to that found in the brain of *G. stagnalis* and *G. fusca*, but the capsules are not so closely crowded together, and the supra-œsophageal commissure lies well forward, not being carried back over the middle of the brain as in *G. stagnalis* (Figure 12). The less crowded condition of the capsules in this species (Figure 5) explains an abnormality in their arrangement observed in the brain of a single individual out of several examined; the two ventral capsules of somite III. (usually found side by side as in *G. stagnalis* and the other species already described) were in this case arranged tandem, just as in ganglia in unabbreviated somites.

Comparing the conditions of the brain capsules in the several species described in this paper, one may say that the larger the leech is, the less are its capsules crowded. This fact seems to indicate that the capsules, and probably the individual ganglion cells also, do not increase in size proportionally with the growth of the leech. This is certainly true of the development of the individual, if not also of the race, for in the very young leech the ganglia of the nerve chain occur in close succession with scarcely any intervening space, whereas in the adult they may be separated by a distance of two rings or even more.

6. *Glossiphonia parasitica* SAY (1824).

Plate 1, Figs. 2, 3a, 3b; Plate 2, Fig. 6; Plate 8, Figs. 32, 33, 37.

Hirudo parasitica Say ('24); *Clepsine parasitica* Diesing ('50); *C. plana* Whitman ('91^a); ? *C. chelydræ* Whitman ('91^a).

a. HABITAT, FORM, SIZE.

This large and conspicuously colored leech is the commonest and most widely distributed of our North American species of *Glossiphonia*. It is often found adhering to the bodies of turtles, whose blood it sucks, or underneath stones in pools and streams frequented by turtles. It is referable to the genus *Placobdella* Blanchard ('94), if one recognizes the validity of that genus. In it are included probably several forms which because of their close relationship I choose to call varieties. One of these has been carefully described by Whitman ('91^a) under the name "*Clepsine plana*." In what follows I hope to supplement that description and add the description of another form which is commonly found associated with it. The two varieties agree completely, so far as I can determine, in form, size, and constitution of somites, but can be distinguished in my collections by constant differences in roughness of surface and in color pattern.

In *general form* the body in this species is very broad and flat. Whitman describes it correctly in the case of large individuals as "ovate-elliptical in contraction, emarginate posteriorly." In the case of small individuals, however, or of large individuals well extended, the emarginate condition is not present (Figure 6, Plate 2; Figure 37, Plate 8; Figure C, p. 56). The dimensions given by Whitman for the largest individuals, I can substantiate: "*Length at rest*, 5-6 cm.; width, 2.6 cm." I have an alcoholic specimen (var. *rugosa*) from Lake Chautauqua, N.Y., which measures 5.6 cm. in length, and 3 cm. in width. Another (var. *plana*) taken from a turtle brought from the Illinois River measures 5.5 cm. in length, 2.3 cm. in width. A living specimen (var. *plana*) taken from a snapping turtle (*Chelydra serpentina*) captured near Cambridge, Mass., measures at rest 5.8 cm. in length, 2.1 cm. in width. Whitman says further: "*Length in extension*, 8.5 cm.; width, 1.8 cm." My living Cambridge specimen attains in extension a length of about 7.5 cm., in which condition its greatest width is 1.5 to 1.7 cm.

b. RINGS AND SOMITES.

The *rings* are distinct except at either end of the body. The furrow between the anterior and middle rings of each somite is, however, less deep than that which separates other rings, for which reason the anterior two thirds of a somite sometimes appears like a single broad annulus, especially at the margin of the body (Figures 2, 2b, Plate 1; Figure 6, Plate 2; Figures 32, 33, 37, Plate 8).

Somites I, II, and XXV.-XXVII. uniannulate (Figures 6, 33, 37), but XXV. and

xxvi. are commonly divided at the margin of the body into a broad anterior and a narrow posterior portion. Somites III. and IV. are biannulate, the broad anterior ring in each case bearing the sensillæ and representing both the anterior and the middle ring of a triannulate somite (Figure 2, III.-VI.). The remaining preanal somites (V.-xxiv., Figure 6) are triannulate, but the posterior annulus of xxiv. is narrower than the adjacent annuli (Figure 6), and the anterior and middle annuli of somite v. are united ventrally while separated by only a very shallow furrow dorsally (7, 8, Figures 2, 3b, Plate 1. These two cases illustrate the centripetal progress of abbreviation (or arrested development), that part of each terminal triannulate somite being affected which is adjacent to an abbreviated somite.

In Figure 32, Plate 8, is shown a rather unusual condition, the apparent disappearance of the furrow separating somites II. and III.¹

The total number of *preanal rings* is sixty-nine, counting somites I., II., and xxv.-xxvii. as uniannulate, III. and IV. as biannulate, and V.-xxiv. as triannulate (Figure 6).

c. EYES, MOUTH, ORAL SUCKER.

The *eyes* appear in the living animal, or in whole preparations, as a single pair closely united and situated in rings 3 and 4 (somite III.). See Figure 6, Plate 1; and Figures 32, 33, Plate 8. An examination of sections, however, particularly of young individuals, shows that there are really three distinct pairs of eyes present, there being a small rudimentary pair anterior, and another still more rudimentary posterior to the principal pair of eyes, exactly as shown for "*C. hollensis*" by Whitman ('92, Figure 6).

All three pairs of eyes² are partially imbedded in a common pigment mass, the anterior and middle pairs being directed forward, the posterior pair backward, just as in *G. elegans* and *G. heteroclita* (Figures 20, 29). The largest

¹ A similar condition is figured by Whitman ('91^a) in his Plate 15, Figure 1. In his text, however, Whitman says (p. 412): "In front of the eyes I was unable to discover any distinct rings. In another species *C. chelydræ*, from Wisconsin, there are three narrow rings in front of the eyes; and the first is marked by the usual metamerie sense-organs. Although no metamerie sense-organs were recognized in front of the eyes in *C. plana*, the correspondence of other metamerie characters in the two species is sufficiently close to enable me to identify the ocular rings as equivalents. The preocular part of the head is, therefore, probably equivalent to the first somite of *C. chelydræ*, and is so numbered in Figure 1."

In view of Whitman's subsequently published studies on "The metamerism of Clepsine" ('92), I think he unquestionably would now recognize *two* preocular somites both in "*C. plana*" and in "*C. chelydræ*"; at any rate, that is the number found in the species which I am describing (Figure 2, Plate 1). Since Whitman has pointed out no other difference between his "*plana*" and "*chelydræ*" than the uncertain one of preocular rings, I consider that their specific distinctness remains to be established.

² Only the largest (middle) pair of eyes appear in the section shown in Figure 2.

(middle) pair is closely united with sensillæ situated in the first ring of somite III. (Figure 2), a fact which Whitman ('92) established for "*C. hollensis*" and which I can completely confirm for the species under discussion (Figure 2).¹

Whitman ('92) further established the fact that the anterior pair of eyes in "*hollensis*" originates in connection with the sensillæ of somite II. He gives no statement as to the origin of the posterior pair. Comparison with *G. elegans* (Figure 29), however, leads me to regard this pair as probably derived from the sensillæ of somite IV. If so, the condition of the eyes in *parasitica* can be derived in its entirety from that found in *G. elegans* by supposing that both the anterior and the posterior pairs of eyes have become rudimentary and been brought close to the large middle pair.

The *mouth* (or., Figure 2) apparently lies between somites I. and II.; in other species it lies farther back, usually in the anterior part of somite III. The *oral sucker* is formed by somites I.-IV., as in other species.

d. REPRODUCTIVE ORGANS.

The *genital pores* are situated in this species exactly as in *G. elegans*; the male (*po. ♂*, Figure 3*b*), between somites XI. and XII. (rings 27 and 28); the female (*po. ♀*), between the middle and posterior annuli of somite XII. (rings 29 and 30).

Testes, six pairs situated intersegmentally in somites $\frac{XIII.}{XIV.} - \frac{XVIII.}{XIX.}$, the usual position in the genus.

The *eggs* are large, white, and opaque. In the vicinity of Cambridge they are laid in May and June, perhaps also in July. In the case of those animals which laid in the laboratory, the eggs appeared to be attached loosely in a single group of fifty or more to the side of the aquarium, rather than to the body of the leech as is the case in the other species studied. The leech remained closely arched over the eggs, — a position from which it was removed only with great difficulty.

e. DIGESTIVE TRACT.

The digestive tract resembles very closely that of *G. elegans*, but has one strikingly distinctive feature: the *salivary glands* (*gl. sal.*, Figure 3*b*), instead of being distributed through several somites in the crop region, are closely aggregated into two compact groups in each half of the body, these groups lying symmetrically, a pair on either side of the proboscis, within somites IX.-XI.

¹ On account of this and other close structural agreements with "*C. hollensis*" as described by Whitman ('92), I was for some time inclined to regard that name as well as "*chelydræ*" as a synonym with *parasitica*, and I have so treated it in a recent publication (Castle, 1900). Professor Whitman, however, has subsequently informed me in a letter that in *hollensis* "there are several pairs of pigmented eyes behind the pair usually recognized as 'eyes.' These are quite conspicuous in the living leech, and I have never seen any such feature in other *Clepsines*." This being so, it is probable that *hollensis* should rank as a distinct species.

The *crop* bears *seven pairs* of lateral diverticula, as in *G. elegans* and the closely related European *G. complanata*, with both of which this species has many points in common. The first pair of diverticula arise in the anterior or middle part of somite XIII. and are two or three lobed, the anterior lobe being prolonged forward through somites XII. and XI. The five following pairs of crop diverticula arise in the middle of somites XIV.-XVIII. respectively, and are usually bilobed distally. The last (seventh) pair of crop diverticula extend far back of their origin in somite XIX., often into somite XXIII. They give off secondary lateral diverticula, a pair in each of the somites through which they extend.

The crop diverticula are often a conspicuous feature of this species when viewed in a living condition from the ventral side of the animal, for numerous large green chromatophores aggregate about the crop and show through the clear ventral body wall the form of the crop outlined in green.

f. NEPHROPORES, NERVOUS SYSTEM.

The *nephropores* (*nph'po.*, Figure 3*b*) open ventrally, anterior to the middle of the sensory ring of a somite, as stated by Whitman ('91^a). They are present in the eighth and all the following triannulate somites.

I have nothing new to add to Whitman's ('92) excellent account of the *central nervous system*. It is important to notice, however, the arrangement of the ventral capsules in the brain region (Figure 3*b*). Those of neuromeres III.-VI. all lie in a single row in the median plane; that is, have what I have called the tandem arrangement. The ventral capsules of neuromere II. (2, 2, Figure 3*b*) have the side-by-side position found in all the species examined by me.

Figure 3*a* is a dorsal view of the brain and shows that the supra-œsophageal commissure in the species lies far forward in what may well be regarded as its primitive position.

The less crowded condition of the brain capsules in this as compared with other species is interesting, as showing that the smaller the leech is, the more crowded are its brain capsules likely to be (compare page 50).

g. PAPILLÆ, COLORATION.

I have reserved to the last, in describing this species, the discussion of papillæ and coloration, for it is on the basis of these characters alone that I am able to distinguish two varieties, *plana* and *rugosa*, which I find associated together, but apparently without intergrading forms, in collections from Cambridge, Mass., Lake Chautauqua, N. Y., Lake Forest, Ill., and Wellsville, Kan., a very wide range extending across the Mississippi valley and the Atlantic seaboard.

(1) *Var. plana Clepsine plana* Whitman, '91^a).

This variety has a relatively smooth skin, which bears dorsally small dome-shaped *papillæ*, the most conspicuous of which are placed as indicated by stars

in Figure 6, Plate 2. They include five longitudinal rows of papillæ found on the middle (sensory) annuli of usually all the triannulate somites. These rows may be designated, from their position, median, marginal, and intermediate, the first named being unpaired, the other two paired.

A row of papillæ is found also between the median and each intermediate row, but these papillæ are situated not on the middle, but on the *posterior* annulus of each of the somites from about VIII. to XXII. inclusive (Figure 6). These will be designated paramedian rows.

The most conspicuous papillæ of somites XXV.-XXVII. are usually placed as indicated in Figure 6. They consist, first, of a continuation of the marginal rows back to the anus; secondly, of two rows of three papillæ each, placed one on either side of the median plane and too near it to fall in the paramedian rows found farther forward.

Other less conspicuous papillæ occur on the dorsal surface of the body and posterior sucker, but no papillæ are found on the ventral surface of the animal.

The general *color* of the body above is brown variegated with yellow, orange, and green. Light areas of yellow or pale orange form:—

I. A median vitta extending from the anterior end of the body back to somite XXV., usually without interruption, but not always so, and expanding commonly at six places, namely, (1) in somites VI. and VII. (Figure 32, Plate 8); (2) in somite IX.; (3) in somites XII. and XIII.; (4) in somites XV. and XVI.; and (6) in somite XXII. (and the posterior part of somite XXI.). The median row of papillæ already described falls entirely in the median light vitta. In somites XXV.-XXVII. both vitta and papillæ become double, dark pigment being found along the median line back to the anus, usually behind it also quite to the posterior margin of the acetabulum. The double (or paramedian) light vitta of somites XXV.-XXVII. contains the three pairs of papillæ shown in Figure 6, Plate 2; it may or may not be continuous with the median light vitta farther forward.

II. Throughout the greater part of the body the papillæ of the intermediate rows lie each in an irregularly rounded light spot. The successive spots of each half of the body may become confluent so as to form an irregular, frequently interrupted, longitudinal band.

III. The margins of the body are conspicuously marked with metameric light spots from about the third or fourth somite back to somite XXV. Some idea of the form and position of these spots may be obtained from an examination of the stippled areas in Figure 6, Plate 2, and Figure 32, Plate 8. Each spot is typically V- or U-shaped and is placed on the adjacent non-sensory rings of two successive somites. The usually hollow centre of the V or U is formed by a spot of brown sometimes bordered with orange. The margin of the sensory ring is generally darker in color than its more median parts, so that it is strongly in contrast with the metameric light spots which it separates.

The posterior sucker is decorated with radially placed triangular light spots (Figure 6) resembling the marginal spots of the body. Other irregularly

rounded light spots may be found on the dorsal surface of the body in light-colored individuals, usually associated with certain papillæ.

There is a certain correlation in the development of light spots in different parts of the body; an animal which has a well-developed median vitta will also have conspicuous marginal and intermediate light spots and vice versa.

The ventral side of the body is much lighter in color, marked only by a few longitudinal bands of dull brown or greenish brown. The number of these bands is either eleven or twelve according as there is present, in addition to five pairs of bands laterally placed, a single broad median band or a pair of narrow paramedian bands separated by an irregular median clear band.

From the under side of the body one can often see in living animals the green pigmented crop diverticula showing through the semi-transparent body.

FIGURE C. — *G. parasitica*, var. *rugosa*. Dorsal view of posterior part of body, showing position and approximate relative size of papillæ. From a Cambridge, Mass., individual.

(2) *Var. rugosa*, var. nov.

The dorsal surface of the body is much rougher in this variety, the *papillæ* being larger, more numerous, and structurally more complex. Instead of being simple, low, and dome-shaped, the more conspicuous papillæ are extended distally in several divergent whitish points, giving the body a decidedly rough, harsh feeling to the touch in the case of hardened specimens. The larger papillæ are likewise rendered more conspicuous by the fact that they are commonly unpigmented, though placed in a generally dark background.

The arrangement of the principal rows of papillæ on the dorsal surface is similar to that in *G. plana*, but with the following easily determined and constant difference. In somites XXIII. and XXIV. (Figure C), the median row of papillæ becomes inconspicuous or disappears altogether, and a large papilla appears on either side of the median line, on the sensory ring of each somite. The ventral surface is free from papillæ as in *plana*.

The *color pattern* is somewhat similar to that of *plana*, but the contrasts are less striking and the colors less brilliant. The general color effect of the dorsal surface is a grayish brown. Marginal spots of light yellow are present, as in *plana*, on the non-sensory rings, but they are smaller and do not extend so far mesiad from the margin of the body. Practically all the larger papillæ appear as small white spots in a generally dark background.

The median vitta is not a continuous light band as in *plana*, but is interrupted at regular intervals by spots of a darker color than the general dorsal surface. It begins as a narrow median light band on the head and neck, constricted or sometimes interrupted in the posterior part of somite VI., less often constricted or interrupted in somite V. also. About in annulus 19, somite IX., begins a narrow dark band which continues to the middle of somite XII. Then come alternating light and dark spots, three of each. A light spot extends over four annuli, a black spot over five as follows: Light spots, annuli 29-32 (Figure 6), 38-41, 47-50; dark spots, annuli 33-37, 42-46, 51-55. Another light spot covers rings 56-64 or 65, broadening out posteriorly so as to include the paired papillæ of somites XXIII. and XXIV. (Figure C). This is followed by a median dark spot extending back past the anus to the margin of the posterior sucker.

The posterior sucker is marked by alternating light and dark rays, very much as in *plana* (Figure 6); it also bears papillæ like those of the body farther forward.

Ventrally the body is light gray in color, owing to the presence there of scattered pigment flecks, which, however, are not arranged in longitudinal bands as in *plana*.

V. MUTUAL RELATIONSHIPS OF THE SPECIES DESCRIBED.

The species described in this paper, with the exception of *heteroclita*, fall naturally into two distinct groups (Figure D, page 58), which may be designated respectively the *stagnalis* and the *parasitica* groups. The former includes the three species *stagnalis*, *elongata*, and *fusca*; the latter, *parasitica* and *elegans*, with the closely related European species, *complanata* and *concolor*. *Heteroclita* occupies a somewhat isolated position intermediate between these two groups.

As arranged in Figure D., the species form a series in which there is from left to right an increasing degree of complexity of structure. This appears from an examination of rugosity, somite structure, crop diverticula, and certain other characters.

In the species of the *stagnalis* group (1) there is a single pair of eyes derived from the sensillæ of somite III., (2) the genital pores are separated by a single ring, namely, the middle (sensory) ring of somite XII., and

(3) the crop diverticula are simple and never exceed six pairs in number. (4) All three species are small, (5) have relatively smooth skin, and (6) at least two of them bear the eggs in clusters attached symmetrically in a double row to the under side of the body, the condition in the third species being unknown.

In *parasitica* and *elegans* (1) there are three pairs of eyes derived respectively from the sensillæ of somites II., III., and IV., (2) the genital pores are separated by two rings, the anterior two rings of somite XII., (3) the crop diverticula number seven pairs and are lobed, (4) the integument is rough and bears papillæ, (5) the attachment of the egg

FIGURE D. Diagram indicating relationships of the species described.

clusters to the body, when such attachment exists, is imperfect and the arrangement of the clusters irregular.

The European species *complanata* and *concolor* are very closely related to *elegans*, *complanata* certainly, perhaps also *concolor*, being intermediate between it and *parasitica*.

In view of the many points of similarity between *parasitica* and *complanata*, there seems to me to be insufficient ground for placing them in distinct genera, as proposed by Blanchard.

Allusion has already been made to the somewhat isolated position of *heteroclita*. In size and in the character of its integument, it resembles the *stagnalis* group, likewise in the number of its crop diverticula; in regard to the lobed condition of its crop diverticula, it resembles the *parasitica* group. In the number of its eyes (three pairs), it likewise resembles the latter group, but the derivation of these apparently is from different somites (III.-V. in *heteroclita*, II.-IV. in *parasitica* and *elegans*.) As regards the position of the genital pores and the way the eggs are borne, it differs alike from both groups.

VI. PARASITES.

Three different endo-parasites, of which I find no notice in the literature, in addition possibly to one already described by Bolsius ('96), infest more or less commonly the species of *Glossiphonia* found in the vicinity of Cambridge, Mass. One of these is a small nematode, another a trematode, these two having been observed in the body of *G. stagnalis* only; the third is a sporozoön found in at least four of the species described in this paper.

In January, 1898, I first observed a minute *nematode* parasite wriggling about in the central lacunar space of a live *G. stagnalis*. Another similarly parasitized leech was found upon further search, and a third was found in the following March, the ovary of the host containing at that time full-grown eggs. The parasite in the last-mentioned case lay close to the contractile dorsal blood-vessel, a very common position for it, as subsequent observations showed. In the spring of 1899 several parasitized individuals were collected and studied; and others were observed in the fall of 1899.

The length of the parasite is about the same in the case of all individuals examined; namely, 1.43 mm. In form, the worm is slender and thread-like, being widest near the middle of its body, where it measures 0.027 mm. in breadth. From there it tapers almost imperceptibly toward either end. The posterior end of the body is sharply pointed; the anterior end blunt, its centre being occupied by the very minute, conical mouth.

Examination of a large number of individuals of *G. stagnalis* in the spring of 1899 showed that between five and ten per cent of the individuals taken from a particular pond, in which the species abounds, contained the nematode parasite. Usually only a single parasite has been observed in the body of a host, but in one case there were three.

The nematode is generally found either coiled up (but not encysted) or wriggling about in the central lacuna (body cavity), in the middle or toward the posterior end of the body. The presence of the parasite does not seem seriously to inconvenience its host, for the parasitized individuals are as large and well developed as those free from parasites, and contain sexual products in equal abundance.

Parasitized individuals were kept in aquaria for several weeks without the occurrence of any noticeable change in the condition of the parasites. This fact and the manifest immaturity of all the parasites examined makes me believe that the leech is an intermediate host and that the

nematode probably attains maturity after passing from the body of the leech into that of another host, perhaps some fish, which feeds upon the leech. How the nematode gets into the body of the leech is likewise unknown, probably from the body of some snail or other small pond animal on which the leech feeds.

The supposed *trematode* parasite I have observed but once, in November, 1899, when three individuals were observed encysted in a single *G. stagnalis*. Unfortunately they with their host died in captivity before I had an opportunity to study them carefully. They lay imbedded in the deeper muscle layers of their host's body, toward its anterior end, each enclosed in a delicate rounded cyst. A single ventral sucker was observed in the parasite and this seemed to lie a little nearer one end of the body. Toward the opposite end, a dark granular substance was observed in the interior of the body, probably in the digestive tube. My study of the parasite, was so incomplete that I should not feel warranted in asserting the absence of a second sucker more nearly terminal in position than the one observed. No measurements of the cysts were made, but I should estimate their diameter roughly at 0.50-0.75 mm.

About half of the individuals of *G. elongata* which have come under my observation contain a *gregarine* which appears to be identical with that described by Bolsius ('96) as occurring in *G. complanata* (Clepsine sexoculata). I have not, however, made a sufficiently careful study of it to enable me to add anything to his account. I find the parasite attached *always to the wall of the stomach diverticula* (Figure 27, *ga.*), never in crop or intestine.

A majority of the individuals of *G. fusca* collected by me contain *sporozoa* in an encysted condition. These parasites are quite common also in the body of *G. heteroclita* and that of *G. elegans*, and I have found them in a single individual of *G. stagnalis*.

Whether or not they represent another stage of the *gregarine* found in *G. elongata*, I am unable to say. As already indicated, I have observed them only in stages of encystment, more or less advanced. One finds the heavily staining sporocyst in whole preparations of its host, usually near the margin of the body, imbedded in the deeper-lying muscle layers (longitudinal and dorso-ventral). The sporocysts which I have observed were spherical in form; the largest ones examined were about 0.13 mm. in diameter and were protected by a thick, dense wall. I have not yet been able to obtain sporocysts containing fully formed

spores. Data, accordingly, are wanting for a full description of this parasite, as well as of the others mentioned, and only a portion of its life history is known. Nevertheless I insert this notice in the hope that some one else may be able hereafter to make use of my fragmentary observations.

EXPLANATION OF PLATES.

All figures were drawn with the aid of Abbé's camera lucida, unless otherwise stated in the explanation of figures.

Arabic numerals in the figures designate rings, which, except in the case of Figures 23 and 27, Plate 6, are numbered from the extreme anterior end of the body backward; Roman numerals designate somites numbered in the same manner.

ABBREVIATIONS.

<i>act.</i>	Acetabulum (posterior sucker).	<i>oc.</i>	Eye.
<i>an.</i>	Anus.	<i>œ.</i>	Cesophagus.
<i>cb.</i>	Brain.	<i>or.</i>	Mouth.
<i>dt. ej.</i>	Ejaculatory duct.	<i>po. ♂</i>	Male genital pore.
<i>ga.</i>	Stomach.	<i>po. ♀</i>	Female genital pore.
<i>gl. d.</i>	Dorsal gland.	<i>pr'b.</i>	Proboscis.
<i>gl. sal.</i>	Salivary glands.	<i>sac. phy.</i>	Pharyngeal sac.
<i>in.</i>	Intestine.	<i>suc. or.</i>	Oral sucker.
<i>i'glv.</i>	Crop.	<i>te.</i>	Testis.
<i>lac. marg.</i>	Marginal lacuna.	<i>va. df.</i>	Vas deferens.
<i>nph'po.</i>	Nephropore.	<i>va. ef.</i>	Vas efferens.
<i>oa.</i>	Ovary.	<i>vs. sem.</i>	Seminal vesicle.

PLATE 1.

- Fig. 1. *G. stagnalis*. Entire digestive tract shown; somite limits indicated by transverse lines, rings not represented. From an entire preparation. \times about 16.
- Fig. 2. *G. parasitica*. Parasagittal section of head end of a small individual taken from a turtle (probably *Chelopus insculptus* Le Conte) bought in a Philadelphia market. Only one (the largest) of the three closely associated pairs of eyes appear in the section.
- Fig. 3. *G. stagnalis*. Ventral view of head end, showing mouth, oral sucker, and the marginal sensillæ and annulation of somites 1.-vi. From an entire preparation. \times 83.
- Fig. 3a. *G. parasitica*. Dorsal view of brain.
- Fig. 3b. *G. parasitica*. Ventral view of anterior part of a small individual obtained from the same source as that shown in Figure 2. From an entire preparation.

PLATE 2.

- Fig. 4. *G. stagnalis*. Diagram showing annulation, central nervous system, reproductive organs (male in left, female in right half of figure), nephropores, etc. The outline of the body was drawn from a whole preparation (\times about 16); everything else is diagrammatic, representing the *average* form and position of organs as determined by examination and comparison of several individuals.
- Fig. 5. Brain of *G. elegans*, ventral view. From an entire preparation. \times 52.
- Fig. 6. *G. parasitica*. Dorsal view of a young individual from Havana, Illinois, partially extended. \times about 10. The starlike structures indicate papillæ; not all of those shown were observed in the individual figured, some being supplied from the study of larger individuals in which the papillæ are more conspicuous.

PLATE 3.

- Fig. 7. *G. stagnalis*. Parasagittal section of anterior part of body. $\times 96$.
- Fig. 8. *G. stagnalis*. Brain viewed from left side. Reconstructed from sections. $\times 208$. Roman numerals designate segmental nerves; Arabic numerals, the ganglionic capsules which supply nerve fibres to same.
- Fig. 9. *G. stagnalis*. Posterior part of ventral ganglionic chain, dorsal view, reconstructed from frontal sections. Arabic numerals designate ventral ganglionic capsules; Roman numerals, metameric nerve bundles. $\times 170$.
- Fig. 10. *G. stagnalis*. Diagram showing the arrangement of ganglionic capsules on the ventral surface of brain.
- Fig. 11. *G. elegans*. Dorsal view of brain.
- Fig. 12. *G. stagnalis*. Dorsal view of anterior part of brain. From frontal sections combined. $\times 167$.

FOSSIL LEPIDOSTEIDS FROM THE GREEN RIVER
SHALES OF WYOMING.

By C. R. EASTMAN.

WITH TWO PLATES.

CAMBRIDGE, MASS., U. S. A. :
PRINTED FOR THE MUSEUM.
AUGUST, 1900.

No. 3. — *Fossil Lepidosteids from the Green River Shales of Wyoming.* By C. R. EASTMAN.

THE Eocene Green River Shales of Wyoming have long been noted for their numerous and beautifully preserved fossil fishes, and large collections have found their way to various American and foreign museums. During the summer of 1899 the Museum of Comparative Zoölogy purchased of Mr. D. C. Haddenham, a local collector at Fossil, Wyoming, two remarkable specimens from the fishbearing shales near that well-known locality. One of these is a gigantic *Lepidosteid*, of which only detached fragments have hitherto been known; the other is a nearly perfect skeleton of a gallinaceous bird. Both specimens are unique in their way, and possess considerable scientific as well as intrinsic value. The news of their discovery was first communicated by Professor Wilbur C. Knight, of Laramie, Wyoming, who made a special visit to Fossil for the purpose of examining the remains, and whose favorable report induced their acquisition.

A brief account of the two specimens, accompanied by a photo-reproduction of the bird, was prepared soon after their arrival in Cambridge, and published in the *Geological Magazine* for February, 1900. Later it developed through correspondence with Mr. F. A. Lucas, Curator of Comparative Anatomy in the United States National Museum, that this Museum had also obtained during the past summer a large cranium of *Lepidosteus* from the same horizon and locality. Another nearly complete fossil gar which had been exhibited at the World's Fair in 1893 was reported, and Mr. Lucas was fortunate enough to ascertain its whereabouts and finally to obtain it too for the national collection. Descriptions of these three specimens are given in the present paper, and it is to be observed that these are the only noteworthy remains of *Lepidosteus* that have yet been found in the American Eocene.

The discovery of fossil gars in the Tertiary of this country was first reported by O. C. Marsh (*Proc. Acad. Nat. Sci. Phil.*, 1871, p. 105). He named two species, *Lepidosteus glaber* and *L. whitneyi*, both from the Eocene of Wyoming; but as no descriptions were given beyond the bare statement that the first "has unusually short vertebræ" and the other

has them "proportionally longer," these names were deservedly rejected by Cope as *nomina nuda*.

A number of species have since been described by Leidy and Cope, all founded on more or less fragmentary remains such as detached vertebræ, scales, and cranial fragments. The only one represented by a tolerably complete individual is *L. cuneatus* (Cope) from the Miocene of Central Utah, the type of which is about 30 cm. in length. The remainder are characterized by A. S. Woodward in his Catalogue of Fossil Fishes as "all too imperfect for specific, and the majority even for generic determination." For instance, Leidy's *L. notabilis* is founded on a single vertebral centrum, which may or may not be identical with those described by him as *L. atrox*. The type species of "Clastes," *L. cycloferus* (Cope), is founded on a few cranial bones and scales. There is still less reason for regarding "Pneumatosteus" as a distinct genus, the type of *P. nahunticus* Cope being an opisthocæalous vertebral centrum from the Miocene of North Carolina.

It is obvious from the foregoing that all the specific titles applied to fossil gars from this country, with the single exception of *L. cuneatus*, have had up to the present time only a provisional significance. They have stood at best for imperfectly definable fragments, which were in some cases with difficulty distinguished from one another. Thanks to the newly discovered material, however, we know what the complete fish in at least two species besides *L. cuneatus* was like, and the cranial osteology of the larger one is as readily decipherable as that of a recent gar. In all, four species are recognized from the American Eocene, and two from the Miocene, as follows:—

L. atrox Leidy (= *L. anax* Cope). Middle Eocene; Wyoming.

L. simplex Leidy. Middle Eocene; Wyoming.

L. notabilis Leidy. Eocene; Wyoming.

L. (Clastes) cycloferus (Cope). Eocene; Wyoming.

L. (Clastes) cuneatus (Cope). Miocene; Central Utah.

L. (Pneumatosteus) nahunticus (Cope). Miocene; North Carolina.

Turning to the European representatives of this family, we find only seven or eight species, likewise founded on fragmentary remains such as scales, vertebræ, cranial fragments, etc., but nowhere a complete skeleton. The range is from Lower Eocene to Lower Miocene, and the distribution sparse in various localities of England, France, and Germany. With pardonable pride, therefore, we may point out that the specimen immediately to be described is at once the largest and most perfect fossil

gar ever brought to light. It lacks any positively archaic features and bears close resemblance to living forms. It is obviously the direct progenitor of the modern Alligator gar, *L. tristæchus* (Bloch and Schneider), and compares with it very favorably both in size and general characters. But if we inquire into the more remote or pre-Eocene history of Lepidosteids, palæontology gives us no answer. They blossom forth suddenly and fully differentiated at the dawn of the Tertiary without the least clue to their ancestry, unheralded and unaccompanied by any intermediate forms; and they have remained essentially unchanged ever since.

Lepidosteus atrox LEIDY.

Definition. — A large species, equalling the recent Alligator gar in size and resembling it in general characters. Head contained about four times in total length; snout short and broad. External bones very heavy, ornamented with ramifying lines of ganoine tubercles which become consolidated into more or less radiating ridges on the operculum and suboperculum. Jaws with an outer series of numerous small teeth followed by a single series of large, regularly spaced, conical, striated teeth implanted vertically in a rather deep and narrow furrow. Dorsal and anal fins remote, nearly opposed; caudal only slightly convex; pelvic situated about midway between the pectorals and anal. Dorsal fin-rays 8, caudal 12, anal 8, pelvic 6. Fulcra biserial and prominent on all fins. Scales very robust, in 18-20 longitudinal series, and between 50 and 60 oblique transverse series counting along the lateral line. Surface of scales smooth or with feeble ornamentation, consisting of pittings and papillæ; posterior margin fimbriate, especially so in scales of abdominal region. Post-clavicular scales prominently sculptured.

Preservation. — Except for the head, the specimen is very well preserved, and the fin-rays remarkably so. Two thirds of the fish, including the head, lies squarely on the ventral surface, but in the abdominal region the body is twisted, so that the right lateral aspect is exposed from the tip of the tail to a point midway between the anal and pelvic fins. The squamation is somewhat

disturbed anteriorly, scarcely at all so posterior to the line of flexure. All the fins with the exception of the pectorals are beautifully preserved, but both pectorals are very defective. Notwithstanding the thickness of its separate plates, the cranial box yielded to pressure of the overlying matrix, and became irregularly flattened prior to fossilization. Most of the external head-bones are displaced, and the only ones escaping serious injury are the opercular apparatus and jaws of the right-hand side. The cranium, therefore, is in a very unsatisfactory condition for study, and it is fortunate our knowledge of its osteology is supplemented by a second specimen, which is described below.

Cranium. — Turning our attention first to the right-hand side of the head, we find that the operculum, suboperculum, interoperculum, preorbitals, maxillary and mandibular ramus all occupy their normal position with respect to one another, being simply flattened out, not displaced. The opercular plates have practically the same configuration and arrangement as in recent species, but are many times more massive, thus harmonizing with the powerful armor-ing of the trunk. The postero-inferior angle of the interoperculum is developed into a stout, blunt process overlapping the suboperculum. The latter plate, together with the operculum, has a slightly different ornamentation from the remaining bones of the head, in that the ganoine tubercles are fused into more or less continuous and radiating ridges. On the jaws and bones forming the roof of the head the tubercular ridges are ramifying and irregularly confluent.

The maxillary is preserved in its entirety and measures 19 cm. in length. Anteriorly it shows a fontanelle as in recent forms, but traces of its segmentation are now nearly obliterated. In the Washington cranium described by Mr. Lucas the segments are very distinct, and are seven in number. (See *infra*, p. 73). As the oral aspect of the maxillary is not exposed, nothing can be affirmed of its dentition. Considering its extreme narrowness, however, and the fact that only a single dental groove is opposed to it in the lower jaw, it is improbable that more than one series of large teeth was present. In this character a noteworthy difference is to be observed between the species under consideration and the recent *L. tristæchus* (= *L. viridis* Gthr.), with which it stands otherwise in close agreement; and incidentally it proves the artificial nature of Rafinesque's subgenus *Atractosteus*. For if we emend the definition of the latter so as to include its nearest allied fossil species, no characters are left by which it can be distinguished from *Lepidosteus s. str.* Hence it seems best to discard altogether the subgeneric terms *Atractosteus* and *Cylindrosteus*.¹

The mandibular ramus is 25 cm. long and composed of the usual parts, dentary, angular, and coronoid. Immediately behind the last-named element are two circumorbital plates, but all the remaining circumorbitals and suborbitals

¹ According to Jordan and Evermann (Bull. 47, U. S. Nat. Mus., pt. 1, p. 109), "The name *Litholepis*, Rafinesque, applied by him to a gigantic gar, *Litholepis adamantinus*, the 'Devil-jack Diamond Fish,' is based on a drawing by Audubon, not intended by Audubon to represent any possible fish."

are crushed into a confused mass. The outer rim of the dentary is set with a series of numerous minute teeth, next to which is placed a single series of large conical teeth implanted vertically in a narrow and moderately deep longitudinal groove. There are nine of these teeth spaced at regular intervals from the symphysis to about the middle of the lower jaw. They are of nearly uniform size, about 2 cm. in height, and vertically striated. Coronal cross-sections show the complicated structure of dentine characteristic of the genus. The symphyseal teeth are directed forwards at a slight angle. The symphyses of both rami lie contiguous to one another in the limestone, but by far the greater portion of the left mandibular ramus and whole of the left maxillary are concealed by overlying bones.

Next above the right maxillary lie a pair of long and narrow, deeply channelled or folded elements, which presumably represent the palatines; and adjacent to these are the median series of bones belonging to the cranial roof, which are now laterally displaced and very considerably injured. The oblique sutures between the frontals and ethmonasals are well shown, and also the sutures along the median line of the head. Premaxillaries and nasals are not preserved, and most of the bones belonging to the otic and occipital region are either missing or crushed beyond recognition. For this reason the length of the head in the median line cannot be accurately determined, although a conservative estimate would place it at about 40 cm. The distance in a straight line from the symphysis of the lower jaw to the posterior margin of the operculum is 45 cm. The right and left clavicle are partially visible behind the head, but are in nowise remarkable either in size or configuration.

Fins. — Very little remains of either of the pectorals, but all the remaining fins are beautifully preserved. The dorsal and anal are triangular, broad-based, and relatively high (20–22 cm.), with eight dermal rays each. These fins are very remote, and nearly opposed to each other. The caudal has a length of 24 cm., is composed of twelve finely articulated long rays and a lesser number of short rays which differ from the rest in being uniserially articulated throughout their length. Prominent biserial fulcra fringe the dorsal and ventral margins of the caudal and front margins of the remaining fins. The extreme tip of the tail is not preserved, but it was apparently very slightly rounded. The pelvic fins are situated about midway between the pectorals and anal, and resemble the latter in form and size.

The long proximal joints of each dermal ray in all the fins consist of two halves, or right and left portions, rather loosely united along the axial plane, and consequently subject to displacement. These proximal pieces correspond in number to the interneurals, which likewise have suffered some displacement in the dorsal and pelvic fins. Immediately after the proximal joint the rays in all fins become biserially articulated, and after a short interval become further bifurcated, much like the arms of crinoids. It will be seen from the following table that little variation in the radial formula exists amongst the various living and fossil species:—

SPECIES.	RADIAL FORMULÆ.	SCALES OF LATERAL LINE.
<i>L. atrox</i> Leidy	D. 8; C. 12; A. 8; P. 6	50-60
<i>L. simplex</i> Leidy	D. 7; C. 12; A. 7 + ?	<i>circa</i> 45
<i>L. tristæchus</i> (Bl. and Sch.)	D. 7-8; C. 12; A. 8; P. 6.	60
<i>L. tropicus</i> Gill	D. 8; C. 12; A. 8; P. 6.	52-54
<i>L. platystomus</i> Raf.	D. 8; C. 12; A. 8; P. 6	56
<i>L. osseus</i> (Linn.)	D. 8; C. 12; A. 7-9; P. 6.	62

Scales.—The body armoring is excessively heavy, being on a par with that of the head, and recalling the powerful dermal defences of *Lepidotus maximus* from the Upper Jura. In fact, these two species probably have the strongest scaly coating of all fossil ganoids. Owing to flexure of the body in the present specimen, with consequent disturbance of the squamation anteriorly, it is difficult to count the longitudinal or even transverse scale-series with accuracy. There are no conspicuously marked scales along the dorsal ridge by which the median line of the back can be determined; but making all due allowance for displacement, the number of longitudinal series in the middle of the body may be set down at between 18 and 20, and of transverse oblique series counting along the lateral line at between 50 and 60. A very large anal scale marks the position of the vent. The exposed surface of most of the scales lying between the tail and middle of the body is smooth, but the posterior margin is strongly fimbriate. Some of the scales lying in advance of the pelvic fins are smooth, but the majority have their central portion ornamented with punctæ, pittings, or channellings, and interspersed with these are occasional papillæ. The lateral line in the present specimen is inconspicuously marked. To give enlarged figures of separate scales is hardly considered worth while, owing to the extensive series illustrated by Leidy and Cope. Those figured by Cope (Rept. U. S. Geol. Surv. Territ., Vol. III. Plate II, Figures 8, 10-12) show the typical ornamentation as well as any, and Figures 47 and 48 show the highly sculptured postclavicular plates.

Vertebræ.—The vertebral column is traceable for the greater portion of its length, although it protrudes only at intervals through the mass of scales so as to exhibit the individual centra. For views of detached vertebræ reference must be had to the works of Leidy and Cope already cited. Stout displaced neural and hamal spines are visible in places along the extent of the vertebral column, and in some places ribs are to be distinguished.

Coprolite.—Accompanying the specimen is a cylindrical coprolite 13.5 cm. long and 5.5 cm. in diameter, which is stated by the collector to have been found in close proximity to the fish. That it is of piscine origin admits of no doubt, and it could hardly have been voided by a smaller species than that under consideration. Its outer surface is marked with a few irregularly spiral folds, but is otherwise smooth. No large hard particles are to be distinguished, and the whole mass bears evidence of very thorough digestion.

Regarding the fine head of *Lepidosteus atrox* (Plate 2) procured by Mr. Charles Schuchert for the United States National Museum while collecting in Wyoming last summer, Mr. Lucas writes:—

"The specimen (Cat. No. 4755) consists of a little more than the anterior half of an individual of about the same size as that belonging to the Museum of Comparative Zoölogy at Cambridge. It lies upon the ventral surface, and while the body has of course been flattened, the cranium has suffered but little from compression, and is almost as favorable for study as a fresh gar would be.

"The general form of the cranium is intermediate between that of *Lepidosteus osseus* and *L. tristæchus*, the muzzle being slightly wider than in the first-named and narrower than in the latter, so that there is no such obvious notch towards the anterior part of the ethmonasals as appears in *L. tristæchus*. At the same time the back of the cranium is proportionately wider in the Eocene than in the living species, the result being that the skull of *L. atrox* tapers somewhat abruptly from behind forward.

"The right vomer is turned outwards exposing its anterior end, and a fracture across the muzzle brings to view a section of the palatines; from these exposures it is possible to state that both vomers and palatines are dentigerous, while in the lower jaw teeth are visible on the dentary. There is no apparent difference between the dentition of *L. tristæchus* and *L. atrox* save that in the present specimen none of the teeth are so large as in the living species. The Cambridge example, however, shows this to be an individual peculiarity. Two nasal plates are present on either side as in existing gars, and the maxillary segments are seven in number, or one more than in the two examples of the Alligator gar available for comparison. The ethmonasals, especially the external sculptured parts, are, as previously noted, narrower in *L. atrox* than in *L. tristæchus*. The frontals are much the same in the two species, but the parietals and squamosals are a little shorter and wider in the fossil than in the living gar. The circumorbitals are displaced and few of them visible, but such as can be seen are notably thick. The same remark applies to the operculum and suboperculum, for although of practically the same size as in *L. tristæchus*, they are decidedly thicker. The cranial bones are also heavy, and their sculpturing while well defined is a trifle finer and decidedly more granular."

PRINCIPAL MEASUREMENTS OF THE WASHINGTON CRANIUM (cf. Plate 2).

Length from extreme tip of nasals to end of supratemporals	34.2 cm.
Length of maxillary	15.6
Length of exposed portion of ethmonasal along suture	12.7
Length of frontals along median suture	13.7
Length of parietals along median suture	4.6
Width across anterior part of ethmonasal	4.6
Width across exposed portion of ethmonasal	2.2
Maximum width across anterior portion of both frontals	5.
Maximum width across posterior portion of both frontals, at junction with squamosals	9.8
Maximum width between outer borders of right and left squamosals	14.

Lepidosteus simplex LEIDY.**Plate 1, Fig. 1.**

1873. *Lepidosteus simplex* Leidy, Proc. Acad. Nat. Sci. Phil., p. 73.

1873. *Lepidosteus simplex* Leidy, Rept. U. S. Geol. Surv. Territ., Vol. I., p. 191, Pl. XXXII, Figs. 18, 26, 31-43. (Vertebrae, jaw-fragments, scales.)

For the opportunity of describing this interesting specimen the writer is indebted to Mr. F. A. Lucas, who obtained possession of it in behalf of the United States National Museum after it had passed into oblivion since being exhibited by a private collector at the Chicago World's Fair. It was derived originally at the typical Green River locality in Wyoming, and bears the catalogue number 4754.

The specific determination is based principally on scale characters, the enamel surface of the few detached scales known to Leidy being described by him as "flat, smooth, and highly polished, and exhibits no markings except one or several minute punctæ near the centre." One peculiar scale, which we can now recognize as belonging to the lateral line and oriented in a wrong position in Plate XXXII, Figure 33, of Leidy's Monograph, is described (Rept. U. S. Geol. Surv. Territ., Vol. I, p. 191) as "traversed fore and aft by a canal communicating by a short cleft with the outer surface. The cleft is directed backward, and is protected by an angular elevation of the anterior border." It would appear to be characteristic of this species that scales of the lateral line are traversed by short vertical canals instead of horizontal clefts, and the remaining scales are flat, smooth, and polished with entire edges. Other distinguishing features will be noted presently, and the definition may be emended as follows:—

Definition. — A species attaining a total length of about 65 cm., of which the head forms one fourth. External bones not especially heavy, arranged as in the recent Alligator gar, but with finer and more granular ornamentation; the ganoine tubercles of operculum and suboperculum forming more or less continuous lines, as in *L. atrox*, but those of the interoperculum fused into irregular ridges. Jaws with an outer series of numerous small teeth followed by a single series of larger ones, the latter, however, relatively of much less size than in *L. atrox*. Vomers dentigerous, but no teeth observed on either palatines or parasphenoid. Fins as in *L. atrox*, but relatively weaker, and dorsal and anal more remote. Scales smooth and highly polished, with entire margins and no ornamentation save for occasional minute punctæ near the centre; scales of the lateral line cleft by a short vertical canal. At least 45 oblique transverse scale-series, and 18 to 20 longitudinal ones. Flank-scales of posterior part of the body considerably elongated in an antero-posterior direction.

Description. — The total length of the fish when straightened out was probably not far from 64 or 65 cm., or exactly four times the length of the head in the median line. In *L. atrox* and *L. tropicus* the head is also contained four times

in the total length, in *L. platystomus* and *L. tristæchus* three and one half, and in *L. osseus* with its specialized snout, but three times. The armoring of the present species is everywhere lighter and simpler than in the massive *L. atrox*, from which it is readily distinguished by its smooth scales with non-fimbriate posterior borders. Another peculiarity which is probably of specific importance consists in the marked elongation of the flanked scales beginning with the series in advance of the anal fin and continuing to the tail. Many of the scales thus affected are twice as long as they are deep, which accounts for there being only 15 oblique transverse scale-series between the base of the tail and base of the anal fin, as compared with 21 such series in *L. osseus*, and 23 in *L. tristæchus* and *L. atrox*. Owing to flexure of the body with attendant disruption of the squamation, it is impossible to state accurately the number of oblique rows, but there were at least 45 of them, and possibly 50.

The head appears to have been nearly severed from the body and turned completely over prior to fossilization, thus exposing the visceral surface to view. This was not accomplished without injury or displacement of certain parts, as witnessed by the position of the left palatine, which shows its oral surface adjacent to the right frontal (above in the figure), while the right mandibular ramus, hyoid arches, and interoperculum are transported to the opposite side of the head (below in the figure). Back of the last-named element is seen from visceral aspect the left clavicle, a strong bone similar in all respects to that of recent gars. The interoperculum differs from the corresponding bone in *L. atrox* in wanting a postero-inferior process, and it is relatively much lighter as well as somewhat smaller. Neither of the maxillæ are preserved, and but one of the mandibular rami; this, the right-hand one, is turned downward so as to conceal most of the teeth, but the articular facets are well shown, and appear exactly as in *L. tristæchus*. Little more can be said of the cranial bones, owing to their confused position and the fact that none of them differ in any appreciable respect from those of recent species.

Of the vertebral column fourteen centra lying in natural order are visible back of the head, their length increasing rapidly from 0.55 cm., beginning with the first, to 0.85 cm. The fins are relatively weaker than in *L. atrox*, especially the caudal, which has fewer short rays, and the dorsal and anal are more remote. The radial formula is as follows: D. 7 (-8?); C. 12; A. 7 (-8?).

TABLE OF MEASUREMENTS.

Length of mandibular ramus	10 + cm.
Length of interoperculum	5.2
Length of hypohyal	0.8
Length of ceratohyal	2.5
Length of epihyal	1.0
Height of clavicle	6.2
Height of caudal pedicle	6.0
Width of basioccipital concavity	1.2
Distance from basioccipital concavity to vomer	16.0

PUBLICATIONS
OF THE
MUSEUM OF COMPARATIVE ZOOLOGY
AT HARVARD COLLEGE.

There have been published of the BULLETINS Vols. I. to XXXV.; of the MEMOIRS, Vols. I. to XXIV.

Vols. XXXVI., XXXVII., and XXXVIII. of the BULLETIN, and Vol. XXV. of the MEMOIRS, are now in course of publication.

The BULLETIN and MEMOIRS are devoted to the publication of original work by the Professors and Assistants of the Museum, of investigations carried on by students and others in the different Laboratories of Natural History, and of work by specialists based upon the Museum Collections and Explorations.

The following publications are in preparation:—

Reports on the Results of Dredging Operations from 1877 to 1880, in charge of Alexander Agassiz, by the U. S. Coast Survey Steamer "Blake," Lieut. Commander C. D. Sigsbee, U. S. N., and Commander J. R. Bartlett, U. S. N., Commanding.

Reports on the Results of the Expedition of 1891 of the U. S. Fish Commission Steamer "Albatross," Lieut. Commander Z. L. Tanner, U. S. N., Commanding, in charge of Alexander Agassiz.

Contributions from the Zoölogical Laboratory, in charge of Professor E. L. Mark.

Contributions from the Geological Laboratory, in charge of Professor N. S. Shaler.

Studies from the Newport Marine Laboratory, communicated by Alexander Agassiz.

Subscriptions for the publications of the Museum will be received on the following terms:—

For the BULLETIN, \$4.00 per volume, payable in advance.

For the MEMOIRS, \$8.00. " " " "

These publications are issued in numbers at irregular intervals; one volume of the Bulletin (8vo) and half a volume of the Memoirs (4to) usually appear annually. Each number of the Bulletin and of the Memoirs is also sold separately. A price list of the publications of the Museum will be sent on application to the Librarian of the Museum of Comparative Zoölogy, Cambridge, Mass.

AUGUST, 1900.

No. 4. — *Characters and Relations of Gallinuloides wyomingensis*
Eastman, a Fossil Gallinaceous Bird from the Green River
Shales of Wyoming. By FREDERIC A. LUCAS.

THE specimen upon which the following observations are based was discovered in the Green River Shales (Middle Eocene) of Fossil, Wyoming, during the summer of 1899, and was shortly after procured for the Museum of Comparative Zoölogy at Cambridge, where it is now preserved (Cat. Foss. Birds, No. 1598). Dr. C. R. Eastman briefly described (Geological Magazine, February, 1900) the bird as *Gallinuloides wyomingensis*, and at his solicitation a more detailed investigation of its structure and relations was undertaken, the results of which are herein set forth.

Like the well-known Green River fishes, the specimen is very complete and in a most excellent state of preservation, although a little injured as to skull, vertebræ, and digits through the over-zealous preparation of the collector. There is a thin, dark, unctuous layer lying on the same plane as the skeleton and almost confluent with the thinner bones, so much so that in developing the finer points it was at times difficult to shun the temptation to carve out a character that might readily be imagined to exist. This layer obscures the ribs, which are scattered, as well as other portions of the skeleton. While, however, many structural details cannot be made out, the general characters are so distinct and the affinities of the bird so apparent that these defects are of comparatively small importance.

The Green River bird was of about the size of a Ruffed Grouse, but stood somewhat higher on its legs. Its galliform nature is obvious at a glance, the most apparent peculiarities being the length of the legs and the depth and the anterior extent of the sternal keel. The majority of its structural resemblances are with the curassows and with the genus *Ortalis* amongst those birds, but while according to Huxley's definition it indisputably falls in the Peristeropodes, there are sufficiently strong characters to exclude it from both the Cracidæ and Megapodiidæ. The bird presents no points of affinity with any of the American grouse, still less with any of the Odontophorinæ.

Cracine and Galline are herein used as short equivalents for "peristeropodous" and "alectoropodous," — the latter terms, although expressing the precise meaning needed, being a trifle cumbersome for ordinary use; "galliform" is employed to designate such characters as are shared in common by all members of the Galliformes.

Head. — The beak much resembles that of *Ortalis*, being moderate in size, stouter than in *Crax*, *Rollulus*, and *Phasianus*; but not so short, stout, and decurved as in *Colinus* and allied genera. The holorhinal narial opening is also much like that of *Ortalis*, and the nasal, which has escaped injury, is typically galliform; the superior process can be clearly seen, but the inferior process is covered on its lower part by crushed bone. The lachrymal, or prefrontal, appears to have been well developed, contrasting in this respect with the American grouse (in which the prefrontal is usually quite small), and agreeing with the curassows. The postfrontal process is stout and directed forwards. The mandible is stout and imperforate, and while it has a blunt angular projection, the recurved process so characteristic of the Galliformes is lacking. This is the most notable departure from the galliform structure found in the skeleton.

Vertebræ and Ribs. — Little can be said of the vertebræ save that the vertebral column presents the customary galliform arrangement of a free vertebra in front of the synsacrum preceded by a mass of anchylosed vertebræ, but as to the number of the latter nothing can be affirmed. The cervicals have suffered from the mistaken zeal of the preparator, and but five can be definitely distinguished between what should be the axis and where the column disappears in the flattened bones of the wings. The caudals are mostly lacking, so that, unfortunately, nothing can be learned from them.

Four pairs of ribs are articulated with the sternum, and at least one pair (one is the customary number in the Galliformes) arose from the synsacrum. Several ribs lie over the synsacrum, but there is no reason to suppose that all of them articulated with it. The usual number of ribs among the Galliformes is five on a side; *Pavo* has six, but the number in the present specimen cannot be made out. There is quite a little space between the first and second costal facets, the succeeding three being crowded together. This is interesting from the fact that it is a feature of modern galline birds, the spacing of the costals being more regular among the curassows.

Shoulder Girdle. — The scapula is not unlike that of *Rollulus*, being long, narrow, and with parallel borders, as in many of the curassows, or

as in *Pediocetes*. The coracoid resembles that of the Old World pheasants, and especially that of *Phasianus colchius*, more than it does the corresponding bone in any of the curassows. The epicoracoid is a little more angular than is customary among Galliformes, but the epicoracoid of *Pediocetes* is of much the same pattern, and in this small point the Green River bird makes its nearest approach to some of the American grouse. The precoracoid process appears to be absent, as it is in most Galliformes, although there is a suggestion of this process in *Arboriphila*. The scapular process is small. The distal end of the coracoid makes a more obtuse angle with the shaft than is usual even in galline birds, but in this respect it is very similar to *Phasianus colchius*.

Scapula, coracoid, and furcula, natural size.

The furcula is unusually short and stout for a gallinaceous bird, exceeding in this respect any species with which it has been compared; it is U-shaped rather than V-shaped, most nearly resembling *Numida* in this particular. There is a distinct though slight acrocoracoid process, so that the furcula did not merely rest against the inner side of the coracoid, but articulated with it, thus differing from all existing Galliformes. The scapular ends of the furcula are hidden so that it cannot be positively stated whether or not they reached the scapula. The hypocleidium is large and triangular, contrasting with *Crax*, which has a spinous hypocleidium, and exceeding *Ortalis*, in which this process is subtriangular and of moderate size.

The sternum has a manubrium of moderate size, but from the disposition of the bones it is impossible to ascertain whether it is perforate or imperforate. Both the external clefts are quite deep, and the external as well as internal xiphoid process is directed well backward; both

processes are expanded at the free end. In the specimens of curassows available for comparison the external xiphoid is not pedate, but there is a suggestion of this condition in *Talegallus*. The sternal clefts are typically cracine, there being no approach to the deep internal cleft which makes the external and internal xiphoids of galline birds really branches of one process. The keel of the sternum is produced more anteriorly than in other Galliformes, though nearly approached by *Centrocerus*. It is to be noted that in this latter form the furcula is unusually long and narrow.

Fore-limb. — The humerus, like the other bones of the wing, is stout and has the deltoid process well developed. The crushing which the bone has undergone prevents its being definitely stated whether or not the humerus was pneumatic, although the probabilities are that it was not. The structure of the wing, in conjunction with that of the sternum, indicates a bird of good powers of flight. The other bones of the wing lie so nearly over one another and are so flattened together that little can be said as to their details, save that the third metacarpal appears to have been much straighter than is usual among gallinaceous birds.

Pelvic Girdle. — As the pelvis lies on its dorsal surface it cannot be stated whether or not it was curved or straight in profile, but in the subequal proportions of the pre- and post-acetabular portions it resembles the curassows, although the conditions are much the same in *Meleagris*. It is somewhat wider in comparison with its length than in the curassows, the proportions resembling those observed in *Thaumalea*. There is no tendency toward separation of the ilia and ischia. The ischia do not seem to be bulged out to overhang the pubes as they do in *Ortalis*, but this feature is so extremely variable in the Galliformes as to have little or no significance. The pubes are long and slender, and as the specimen now lies, they appear parallel with one another throughout their distal halves. In most Galliformes the pubes approach each other distally, sometimes, as in *Ortalis* and *Penelope*, being almost in contact. In this respect the Green River specimen departs from the cracine type and approaches such forms as *Meleagris* and *Rollulus*, and while it is of course possible that the pubes may have approached each other in the living bird, the intervening space is now so great as to make this seem doubtful. The prepubis is small, the obturator foramen very small, and the ilio-ischiadic space moderate.

Hind-limb. — The femur is so crushed as to obscure its characters. There is no sign of a patella, though this may have been present. The cnemial ridges are slight, and there is the customary osseous tendinal

bridge on the anterior face of the distal end of the tibia. The fibula is of the same general proportions as in other Galliformes.

The hypotarsus is very likely only grooved, not perforate; but this is one of the points that cannot be definitely ascertained without injury to the specimen. The number of tarsal tendinal perforations is a character of much importance in birds, for it seems fairly constant within the limits of a given large group and indicates the amount of specialization attained by the members of that group. As all Galliformes examined have a single tendinal perforation, the absence of such a character would indicate that our Eocene bird is of a more primitive type than its modern relatives. The usual tarsal sesamoid shows back of the right tarsal joint. The tarsus is longer in proportion to the tibia than in any other species examined, as is shown by the subjoined table, which gives the length of these bones in a few species:—

SPECIES.	LENGTH OF TIBIA.	LENGTH OF TARSUS.	RATIO.
<i>Gallinuloides wyomingensis</i>	57° mm.	45° mm.	1.27
<i>Penelope superciliaris</i>	115.	82.	1.40
<i>Rollulus roulroul</i>	72.	48.	1.50
<i>Phasianus colchius</i>	112.	72.	1.56
<i>Ortalis macalli</i>	108.	65.	1.66
<i>Colinus virginianus</i>	53.	30.	1.77

The toes are moderate and slender, of about the same length as those of *Colinus virginianus*, but a little heavier; yet they are not heavy in comparison with the size of the tarsus or the general bulk of the bird.

The following table gives the length of the principal bones in the skeleton, all measurements being made in a straight line:—

PRINCIPAL MEASUREMENTS OF GALLINULOIDES WYOMINGENSIS.

Occipital condyle to tip of bill,	47.° mm.	Xiphoid to anterior end of keel,	59 + mm.
Humerus,	47.	Femur,	41.
Ulna,	49 +	Tibia,	57. +
Metacarpus,	25.	Tarsus,	45.
Scapula,	48.	Basal phalanx of digit I.,	7.5
Coracoid,	29.	do do do II.,	11.
Xiphoid to manubrium,	59. +	do do do III.,	12.
		do do do IV.,	7.5

Relationships.—The various characters of the Green River bird may be summarized as follows:—

Galline Characters. — Pedate end of internal xiphoid process, arrangement of the costal facets, and shape of the distal end of coracoid.

Cracine Characters. — Blunt, upright, subtriangular costal process, shallow inner sternal notch, small prepubis, proportions of pelvis, elongate tarsus with all the toes on the same level.

Peculiar Characters. — Absence of recurved mandibular process; short, stout, U-shaped furcula with large hypocleidium and articular facet for coracoid.

The weight of the peculiar characters, particularly the absence of a post-angular process, are, as stated in the introductory remarks, sufficient to prevent the bird being placed in either the Cracidae or Megapodidae, thus necessitating the establishment of a new family, Gallinuloididae. The principal family characters are the absence of a postangular mandibular process, presence of an articular facet on the furcula for the reception of the acrocoracoid, and the presence of an acrocoracoid.

The generic characters are considered to be the stout U-shaped furcula, the shape of the scapula, and the anterior extent of the *crista sterni*. As specific characters are always comparative, none can be formulated from a single specimen, even did they not depend to so great an extent in birds — often entirely — on external features.

This bird is interesting not because it presents any striking peculiarities of structure, but rather because it does not, and because it belongs, as we might naturally expect from its age, to a generalized type having points of structural resemblance with various families of gallinaceous birds. It is an additional reminder, were any needed, of the great gaps in our knowledge of the development of birds and of the rapidity with which they attained their present forms. The mammals of the Eocene are quite different from existing species, but this bird readily takes its place among the forms of to-day.

The following Publications of the Museum of Comparative Zoölogy
are in preparation:—

PUBLICATIONS
OF THE
MUSEUM OF COMPARATIVE ZOÖLOGY
AT HARVARD COLLEGE.

There have been published of the BULLETINS Vols. I. to XXXV.; of the MEMOIRS, Vols. I. to XXIV.

Vols. XXXVI., XXXVII., and XXXVIII. of the BULLETIN, and Vol. XXV. of the MEMOIRS, are now in course of publication.

The BULLETIN and MEMOIRS are devoted to the publication of original work by the Professors and Assistants of the Museum, of investigations carried on by students and others in the different Laboratories of Natural History, and of work by specialists based upon the Museum Collections and Explorations.

The following publications are in preparation : —

Reports on the Results of Dredging Operations from 1877 to 1880, in charge of Alexander Agassiz, by the U. S. Coast Survey Steamer "Blake," Lieut. Commander C. D. Sigsbee, U. S. N., and Commander J. R. Bartlett, U. S. N., Commanding.

Reports on the Results of the Expedition of 1891 of the U. S. Fish Commission Steamer "Albatross," Lieut. Commander Z. L. Tanner, U. S. N., Commanding, in charge of Alexander Agassiz.

Contributions from the Zoölogical Laboratory, in charge of Professor E. L. Mark.

Contributions from the Geological Laboratory, in charge of Professor N. S. Shaler.

Studies from the Newport Marine Laboratory, communicated by Alexander Agassiz.

Subscriptions for the publications of the Museum will be received on the following terms : —

For the BULLETIN, \$4.00 per volume, payable in advance.

For the MEMOIRS, \$8.00 " " "

These publications are issued in numbers at irregular intervals; one volume of the Bulletin (8vo) and half a volume of the Memoirs (4to) usually appear annually. Each number of the Bulletin and of the Memoirs is also sold separately. A price list of the publications of the Museum will be sent on application to the Librarian of the Museum of Comparative Zoölogy, Cambridge, Mass.

Introduction.

OUR present ideas of homology in the details of insect mouth-parts rest almost exclusively upon anatomical data, and need careful revision in the light of embryological facts.

Too many entomologists have speculated upon the subject in complete disregard of evidence from ontogeny or phylogeny. Embryologists, on the other hand, have greatly neglected the mouth-parts.

It seems almost superfluous to insist that highly specialized organs can be but imperfectly understood unless studied in egg and larva as well as imago; that generalized types illuminate specialized forms; and that equivalent groups are linked together through their more generalized members; yet too often these accepted principles are not applied.

The objects of the present paper are two: first, to supplement my previous account (Folsom, '99) of the anatomy and functions of the mouth-parts of a representative Collembolan; second, to discuss the morphology of mandibulate mouth-parts of insects and their nearest allies upon anatomical and embryological evidence derived from the most primitive insects, the Apterygota.

¹ Contributions from the Zoölogical Laboratory of the Museum of Comparative Zoölogy at Harvard College, E. L. Mark, Director, No. 114.

My comparisons have been hindered by the scanty and fragmentary nature of published embryological observations upon the mouth-parts of Arthropods. Detailed studies upon the subject in the less specialized Pterygota, Crustacea, Arachnida, Diplopoda, and Chilopoda do not exist, but are necessary for the proper understanding of the morphology of the mouth-parts, and will have much bearing upon the phylogeny of the classes named.

The present study was made under the supervision of Dr. C. B. Davenport, to whom I am most grateful for his constant, critical supervision, valuable advice and encouragement.

Professor E. L. Mark has carefully revised the text and attended to all the details of publication; his help, as always, has been of inestimable value to me.

Methods.

For killing eggs, and adults as well, simply hot water was used, with excellent results. After killing, material was carried through several successively stronger grades of alcohol and finally preserved in absolute alcohol.

In the study of the embryo, both dissections and serial sections were made. As much as possible was learned by dissection, as that method, although difficult, gave more trustworthy results than could possibly be obtained by reconstruction from sections. The germ bands of freshly killed embryos were too delicate to be dissected out uninjured; but after being in absolute alcohol for two months they had become sufficiently hardened for this operation. A longer stay made them brittle, but advantageously so in some respects.

Dissections were made under a compound microscope with a magnification of about one hundred and fifty diameters. For the finest work, the "minutien Nadeln," used by entomologists for pinning minute insects, were employed. The general form and position of an embryo could be seen through the transparent egg-membranes; but to get clearer views, the outer membrane was removed, the remaining corrugated membrane punctured, and a staining fluid allowed to penetrate the germ band. Preparatory to the dissection of minute structures, the egg was placed in weak glycerine, which caused the embryo to shrink away from the membranes slightly, allowing these to be removed; the germ band was dissected out and stained with Grenacher's alcoholic borax-carmines or hæmatoxylin. Isolated parts of the embryo were mounted temporarily in weak glycerine without pressure, in such a

way that by moving the cover glass they could be rolled into various desirable positions.

For sectioning, portions of the embryo, or punctured eggs, were imbedded in hard paraffine. The eggs required at least four hours for thorough penetration. For orienting, Woodworth's ('93) method was employed, but not always with success, as the objects were liable to become distorted or even lost. A simpler, but more efficient, method for these particular objects was to orient them under the compound microscope with a hot needle in a glycerine-smeared watch-glass of melted paraffine, and to fix them in place by touching the glass beneath with cold water before hardening the paraffine throughout. When the block of paraffine was inverted under the compound microscope, the imbedded object could be seen through a thin film of paraffine, and a scratch could be made to indicate the plane of sectioning.

Sections from 5 to 10 μ in thickness were cut with either a Reichert or a Minot-Zimmermann microtome, fastened with Mayer's albumen mixture, and stained with various reagents, chiefly Delafield's or Kleinenberg's hæmatoxylin followed by safranin, Grenacher's alcoholic borax-carmin, and Heidenhain's iron-hæmatoxylin.

General Description of Egg.

The eggs of *Anurida maritima* are spherical, from 0.26 mm. to 0.38 mm. in diameter, enlarging with age, and at first light yellow, later becoming orange.

They occur abundantly along the Atlantic coast under stones between tide-marks, and are usually mingled with the conspicuous white exuviae of the parents.

The eggs of *Collembola* depart widely from those of other insects by being holoblastic; they are slightly unequal in cleavage. After the morula stage the outer nuclei and accompanying protoplasm migrate toward the periphery, leaving behind yolk masses and also cells which subsequently prove to be entodermal. The peripheral cells become arranged in two layers: the ectoderm, a continuous superficial layer, with nuclei at regular intervals, and the mesoderm, an inner, less compact layer with fewer and scattered nuclei. Thus there soon results a condition like that derived from superficial cleavage. The ventral plate, or germ band, is formed by migrant mesoderm cells, and, according to Uzel ('98, p. 22, *Tomocerus*), is first represented by two pairs of isolated thickenings, — the procephalic and mandibular fundaments. I have found

that the appendages appear in succession from in front backward, and that they are well developed long before the segmentation of the germ band. The blastoderm is interrupted only by the "dorsal organ," which is attached to the inner egg membrane.

Claypole ('98, pp. 255-258) distinguishes five egg membranes in Anurida, and maintains that all arise from the egg or the blastoderm. I find that in the ripe egg two are evident: a thick outer and a thin corrugated inner one, respectively analogous to, if not homologous with, the chorion and the vitelline membrane of other insects. Another delicate membrane completely envelops the embryo in early stages (Plate 1, Figures 1, 3, *mb.*), except where interrupted by the dorsal organ. I have found it to be, not a "larval skin," but a blastodermic membrane.

The peculiar cleavage of Collembola has been observed by Oulganine ('75, '76), Lemoine ('83), Claypole ('98), and Uzel ('98). In the most nearly related group, Thysanura, the cleavage has been shown to be superficial by Grassi ('85), Heymons ('96, '97^a), and Uzel ('97, '98). In cleavage, then, Collembola resemble many Crustacea and Arachnida, in which it is at first total and secondarily superficial.

Thysanura, on the other hand, approach the Orthoptera, in that the cleavage is from the first superficial.

The "dorsal" or "precephalic" organ of Collembola has been described by Lemoine ('82), Wheeler ('93), Claypole ('98), and Uzel ('97, '98); of Thysanura, by Grassi ('85), Heymons ('96, '97^a), and Uzel ('97, '98). Wheeler homologized it with the "indusium" of Orthoptera, and suggested its analogy with the embryonic sucking-disk of Clepsine. Claypole collected evidence of a similar structure in Crustacea, which has been reinforced by Uzel.

Reference Stages.

For descriptive purposes I have selected nine consecutive stages of development, which may be identified in the entire egg by the following characteristics:—

At Stage 1 (Plate 1, Figure 1) the embryo is almost spherical with all the primary appendages represented by small papillæ. The dorsal organ is large, with a spherical imbedded portion and an expanded superficial part, the latter firmly attached to the corrugated membrane. This stage is very nearly that of Claypole's ('98, Plate XXIII.) Figures 40 and 41 of the same species.

Stage 2 (Plate 1, Figure 2) is characterized by folds representing the

last five abdominal segments, and by longer appendages, of which the antennæ and legs show traces of segmentation. It is approximately the stage of Figures 42 and 47 of Claypole.

At Stage 3 (Plate 1, Figure 3) the ventral surface of the embryo is almost flat, preparatory to involution; the legs are decidedly longer, and the fundament of the proctodæum is distinct. Figures 43 and 43^a of Claypole belong near this stage; also Figure 10 of Ryder ('86), likewise for *Anurida maritima*.

During Stage 4 (Plate 1, Figure 4) the germ band is folding into the yolk, the fold beginning anteriorly and continuing backward. The antennæ and legs are long and stout. My figure shows a stage a little later than that of Figure 44 by Claypole.

At Stage 5 (Plate 1, Figure 5) the involution has reached the centre of the egg, the antennæ and legs are distinctly segmented, the mouth-folds are conspicuous, and the dorsal organ has shrunk considerably.

Stage 6 (Plate 1, Figure 6) is much like the last, except that the head and tail of the embryo have approached each other. The dorsal organ is much reduced and somewhat flask-shaped. This is the stage of Ryder's Figure 7.

At Stage 7 (Plate 2, Figure 7) the eyes are first recognizable as five black circular patches on either side. Figure 45 of Claypole represents this condition.

Stage 8, which I have not figured, differs externally from the last in that the number of eyes is no longer evident, it being obscured by a suffusion of pigment. The degenerating dorsal organ now disappears by resorption.

Stage 9 (Plate 6, Figure 41; also Claypole, Figure 48) refers to the newly hatched insect. Before this period, movements of the insect may be seen through the egg membranes. If eggs have been kept dark, — the normal condition, — the emerging insects are white, excepting the eyes; if exposed to sunlight, however, the embryos become blackish-blue long before hatching. At emergence the external clothing of setæ is complete, and the mouth-parts are fully formed.

Procephalic Lobes.

The fundaments of the procephalic lobes are two isolated thickenings of the blastoderm, which are the first of the paired fundaments to appear. Each procephalic fundament is lenticular in form and rapidly increases in thickness and area. In the earlier stages the procephalic

thickenings are not definitely circumscribed, but merge insensibly with the rest of the blastoderm.

Previous to Stage 1 the procephalic lobes meet in the median plane, where the labral fundament then appears. Before the appearance of the labrum, however, the antennal fundaments evaginate from the posterior regions of the procephalic lobes.

In Stages 1 and 2 (Plate 1, Figures 1 and 2) the lobes continue to increase in area and thickness.

At Stage 3 either lobe is relatively as thick as is represented in Figure 3, *pr'ceb.*, and in lateral surface views (Plate 2, Figures 9, 10, *pr'ceb.*) appears as a strongly convex, oval protuberance.

In Stages 4 (Plate 3, Figure 12, *pr'ceb.*) and 5 (Plate 3, Figures 19, 20, 21, *pr'ceb.*) the procephalic lobes change little except in size, and the median depression between them (*sul.*) is still distinct.

In Stage 7 (Plate 5, Figure 30) the depression (*sul.*) becomes obliterated, and the eyes (Plate 4, Figure 24, *ocl.*) and postantennal organs (Figure 24, *o.p'at.*) appear. At this stage sections show a pair of ganglionic fundaments (Plate 4, Figure 28, *pr'ceb.*), the largest and most anterior in the head, with which the next two pairs eventually unite to form the supra-oesophageal ganglion of the adult (Plate 8, Figure 51, *gn.su'æ.*).

In other Collembola the procephalic lobes develop in just the same way, as may be gathered from Nicolet ('42, *Smynthurus*), Packard ('71, *Isotoma*), Lemoine ('83, *Smynthurus*), and Uzel ('98, *Tomocerus*).

Also in Campodea the same course of development is followed (Uzel, '98, Taf. 3, Figures 33-36; Taf. 4, Figures 37-42) as well as in *Lepisma* (Heymons, '97^a).

In fact, the simple process described for Anurida characterizes not only Orthoptera (Ayers, '84, Wheeler, '93, Heymons, '95), but also insects in general.

The procephalic lobes of Diplopods and Chilopods develop essentially as in insects and Crustacea, but no detailed comparisons can be made as yet.

The most interesting considerations concerning the ocular segment of Hexapoda relate to its equivalence with the first segment of Crustacea.

Viallanes ('87, pp. 98-109) has carefully compared the brain in both classes and found a striking agreement, extending to histological details:

“Considérons en premier lieu la partie latérale du protocérébron, connue des anatomistes sous le nom de ganglion optique; elle nous montre d'abord, en allant de dehors en dedans, les parties suivantes: les fibres

post-rétinennes, la lame ganglionnaire, le chiasma externe, la masse médullaire externe, le chiasma interne et la masse médullaire interne.

“Toutes ces parties, si nettement caractérisées, se retrouvent sans modification chez l’Insecte ; il n’est donc pas douteux qu’il existe au moins pour cette première région du ganglion optique similitude complète entre les deux types que nous cherchons à comparer. . . . Cette similitude a été reconnue par tous ceux qui se sont occupés de ce sujet (Berger, Bellonci, Carrière et moi). . . . En somme, au point de vue des parties dont nous venons de parler, il n’existe que des différences bien peu importantes entre l’Insecte et le Crustacé : chez le premier, les deux lobes cérébraux sont très rapprochés et se soudent sur la ligne médiane ; chez le second, ces mêmes parties (appelées balles supérieures) sont écartées, chacune d’elles étant logée dans le pédoncule oculifère correspondant.”

Packard '98, p. 51) says, “Hence the ocular segment, *i. e.*, that bearing the compound and simple eyes, is supposed to represent the first segment of the head. This, however, does not involve the conclusion that the eyes are the homologues of the limbs, however it may be in the Crustacea.” As Viallanes has proved the equivalence of protocerebrum and optic nerves in insects with those of Crustacea, and others have shown that the compound eyes of both groups are constructed alike, even to the number of retinal elements, it is proper to infer that the compound eyes of the two groups are homologous.

The protocerebrum of Collembole and Thysanura agrees in development and structure with that of other insects and also with decapod Crustacea ; the faceted eyes of Hexapoda and Crustacea are likewise homologous.

Labrum and Clypeus.

The labrum is chiefly interesting because it has frequently been held to represent a pair of primary appendages.

At Stage 1 (Plate 1, Figure 1 ; Plate 2, Figures 8, 8^a, *lbr.*) the labrum (really clypeo-labrum) is a median hemispherical papilla anterior to and distant from the bases of the antennæ ; at no period does it give evidence of a paired origin.

At Stage 2 (Figure 2), while the distances between the labrum and mandibles is precisely the same as in the preceding stages, the antennæ are inserted beside the oral region of the upper lip ; the latter is globular and flattened against the egg shell.

Surface views at Stage 3 (Figure 3) are given in Figures 9, 10, and 11, *lbr.*

A sagittal section at this stage shows (Plate 3, Figure 13) an elongation of the labral fundament, and demonstrates its origin from the germ band by simple evagination. The posterior surface of the labrum is now the anterior wall of a distinct invagination (*or.*), the fundament of the stomodæum.

At Stage 4 (Figure 4) the labrum is longer (Plate 3, Figure 19, *lbr.*) and its long axis has swung backward, probably on account of the excessive elongation of the anterior labral surface. A ventral aspect of the germ band (Figure 12) shows the labrum to be approximately oval in cross-section, but with a more rounded anterior surface.

At Stage 5 (Figure 5) the labrum (Plate 3, Figure 20, *lbr.*) is decidedly longer. The basal part of the labral fundament represents the clypeus, with which the lateral folds, or mouth-folds (Figure 21, *pli.or.*) are now confluent; overhung by the end of the labrum is the distinct stomodæum.

At Stage 7 (Figure 7) a distinct depression (Plate 5, Figure 31, *dep.*) separates the clypeus from the procephalic lobes; the depression, in fact, may be seen as early as Stage 1, for it simply forms the angle between the labral fundament and the procephalic lobes. Although the clypeus merges insensibly into the cheeks, the labrum is a free trapezoidal plate, as in the adult (Plate 6, Figure 40, *lbr.*). The antennæ are now inserted (Plate 4, Figure 24, Plate 5, Figure 30, *at.*) almost exactly opposite the base of the labrum. At this stage the clypeo-labral suture is not distinctly indicated (Figure 24), but in Stage 8 an invagination occurs to form the labral hinge of the adult (Plate 6, Figure 40, *atc.*).

In Stage 8 the only other important changes in the labrum are the evagination of single hypodermis cells to form the external setæ, and the formation of trivial cuticular folds which represent the rudiments of the epipharynx. In *Anurida*, as in *Orchesella*, the epipharynx is purely a cuticular structure and unconnected with the central nervous system.

In the adult *Anurida* a shallow clypeo-frontal groove is distinguishable (Plate 6, Figure 40, *sul.*), but does not amount to a suture, and the clypeus is not laterally demarcated from the groove. In *Orchesella* and *Tomocerus*, however, the clypeus is a distinct sclerite. In none of the *Collembola* that I have studied is there any distinction between clypeus and labrum on the roof of the pharynx.

Packard ('71, p. 18) says, regarding *Isotoma*, "The clypeus, however, is merged with the epicranium, and the usual suture between them does not appear distinctly in after life, though its place is seen in Figure 13 to be indicated by a slight indentation. The labrum is distinctly defined by a well-marked suture, and forms a squarish knot-like protuberance, and in size is quite large compared to the clypeus. From this time begins the process of degradation, when the insect assumes its *Thysanurous* characters, which consist in an approach to the form of the *Myriapodous* head, the front, or clypeal region being reduced to a minimum, and the antennæ and eyes brought in closer proximity to the mouth than in other insects."

Lemoine ('83, p. 510, Planche XV., Figure 24) mentions in *Smynthurus*, "Les deux appendices qui constitueront la lèvre supérieure," but they appear in his figure as only simple lobes from a large, median labrum.

Wheeler ('93, p. 57, Figure VI.) represents the labrum of *Anurida* as a median, unpaired fundament, and Claypole ('98, Plate XXIII.) gives several surface views of the upper lip in the same species.

Uzel ('98, Taf. VI., Figur 87) shows the single labral fundament of *Macrotoma* (*Tomocerus*).

Regarding *Campodea*, Uzel ('98, p. 26) says: "Vor der Mundeinsenkung erblickt man jetzt schon die unpaare Anlage der Oberlippe," and partially illustrates (Taf. IV., VI.) the development, which proceeds essentially as in *Anurida*.

The finished labra of *Campodea* (Grassi, '86^b, Tav. IV., Figura 7) and *Japyx* (Grassi, '86^b, Tav. II., Figura 15 *bis*) are very simple rounded plates.

For *Lepisma*, Heymons ('97^a, Taf. XXX.) figures the labral fundament as a prolongation from the procephalic lobes, and characterizes it (p. 591) as "eine kleine, vollkommen, ungetheilte, einfache Platte." Later (p. 593) he says, "Die Oberlippe wird bedeutend grösser und bekommt an ihrem hinteren Rande eine mediane Einkerbung (Figure 17)." The median indentation is clearly, however, a secondary formation.

In both *Lepisma* and *Machilis* (Oudemans, '88, Taf. I., Figur 3) the labrum remains simply an anteriorly rounded plate.

In the Orthopteran *Æcanthus*, Ayers ('84, p. 240, Plate 18, Figures 21, 22) describes the unpaired fundament which forms the ovate labrum. In short, the labrum in all Orthopteran families develops from an unpaired fundament. (See Wheeler, '93, Heymons, '95^b.)

The same is true of the *Libellulidæ* and *Ephemeridæ* (Heymons, '96,

Taf. II., Figuren 19, 29), and examples might be multiplied to show that the labrum does not represent a pair of appendages. The view held by Kowalevsky, Carrière and others, that it did, was based chiefly upon anatomical evidence, which has since been disproved by Heymons ('95) and others. (See Packard, '98, pp. 42-43.)

Scolopendrella (Latzel, '84, p. 8, Taf. I., Figur 4; Grassi, '86^a, p. 15, Tav. II., Figura 6) has a simple, emarginate, six-toothed labrum, and, like Hexapoda, a distinct, subtriangular clypeus. Moreover, as Packard ('98, p. 22) has affirmed, it has a V-shaped tergal suture, which exists also in the more generalized insects, but is absent in Myriopods.

In Diplopoda, an upper lip is present as a transverse plate, fused, however, with the cranium.

In Chilopoda, a similar labrum is present, but is not always basally fused, and frequently consists of three transversely placed sclerites. It originates as a simple median lobe (Heymons, '97^b, p. 4, Figur 1, Scolopendra).

In Crustacea the upper lip is derived from a median, unpaired evagination corresponding almost exactly in position with the labral fundament among insects.

Among insects, then, the labrum and clypeus develop from a median evagination between the procephalic lobes, and give no satisfactory evidence of paired origin. The same statement applies also to Crustacea, and, as far as is known, to Myriopods.

Antennæ.

The antennæ are the first paired organs to appear. They develop from the posterior boundaries of the procephalic lobes, and at Stage 1 (Plate 1, Figure 1, Plate 2, Figure 8, *at.*) are stout cylindrical papillæ already faintly constricted into two segments. As Figure 8 shows, they are more lateral than the other paired fundaments, and at first far behind the labrum. Sections prove them to be simple ectodermal evaginations, like all the other appendicular fundaments.

At Stages 2 and 3 (Plate 1, Figures 2, 3, *at.*) the antennæ are longer and usually composed of three segments. In Figure 2 the fourth segment, which normally appears later than Stage 2, is suggested. They have now moved forward to positions near the labrum; in Stage 4 (Plate 1, Figure 4; Plate 3, Figure 12, *at.*) they lie on the two sides of that appendage, and in Stage 5 (Plate 1, Figure 5; Plate 3, Figure 21, *at.*) they have attained a position farther forward than the upper lip.

In Stage 6 (Plate 1, Figure 6, *at.*) there is clearly indicated a fourth antennal segment, which in Stage 7 (Plate 2, Figure 7; Plate 4, Figure 24, *at.*) becomes more distinct. At this time the antennæ are long and stout, and occupy a position still farther forward than before.

At hatching (Plate 6, Figure 41) they are pre-oral, more slender, distinctly segmented, and clothed with setæ.

Elongation of the antennæ occurs throughout their entire length, judging from the number of cells in longitudinal alignment on the same segment at different stages of growth, and also from the frequency of karyokinesis in different parts of the appendage. Growth is more rapid, however, in the apical region, from which the segments are successively constricted. In all the oral fundamentals, in fact, growth was inferred to be most rapid at the apex, although likewise occurring throughout the rest of the ectodermal layer. At the apex itself — and these remarks apply equally well to the legs — the hypodermal cells are larger and more turgid than elsewhere, projecting as minute lobes from the surface. The chromosomes are very small, but frequently so arranged as strongly to suggest mitotic division.

At Stage 5 (Plate 4, Figure 28, *deu'ceb.*) an antennary ganglion supplying the antennal nerves, becomes evident, but finally fuses with the first and third ganglia, between which it lies, to form the supræesophageal ganglionic mass.

In Thysanura the antennæ develop essentially as I have described for Collembola, being likewise at first post-oral and subsequently pre-oral, as Uzel ('98) has shown for Campodea and Heymons ('97^a) for Lepisma. Such a migration of the antennæ is, however, not peculiar to Apterygota, but is characteristic of all insects.

Among Diplopoda but a single pair of antennal fundamentals occurs (Heymons, '97^b, p. 7, Figur 2, Glomeris). Judging from their position in relation to the mouth, they are equivalent to the antennæ of Chilopoda, among which Heymons ('97^b, p. 4, Figur 1, Scolopendra) has discovered two pairs of antennal fundamentals. The præ-antennal rudiments in Chilopoda appear to represent the antennæ of insects and the antennules of Crustacea, the second pair to be equivalent to the intercalary appendages of insects and the antennæ of Diplopods and of Crustacea.

It can scarcely be doubted, in view of the researches of Viallanes ('87), that the antennæ of insects are homologous with the antennules of Crustacea. In the author's words ('87, p. 105): "Voyons maintenant le deuxième renflement cérébral du Crustacé décapode. Il est formé d'une

paire de masses nerveuses ventrales connues sous le nom de *lobes olfactifs*, réunies l'une à l'autre par une commissure transverse, et d'une paire de masses dorsales qu'on pourrait désigner sous le nom de lobes dorsaux.

"Les lobes olfactifs ont une structure tout à fait spéciale; la substance ponctuée qui entre dans leur constitution est, pour ainsi dire, 'segmentée' en un grand nombre de petites boules d'aspect absolument caractéristique, qu'on désigne sous le nom de *glomérules olfactifs*. Les lobes dorsaux, au contraire, n'ont dans leur structure rien qui soit spécifique.

"Le nerf antennaire naît du deuxième renflement cérébral par deux racines, — l'une sort du lobe olfactif, l'autre du lobe dorsal; ce dernier, en outre, donne naissance à un nerf tégumentaire.

"Cette description du deuxième segment cérébral du Crustacé peut, et sans qu'il y ait aucun changement à y faire, s'appliquer à l'Insecte, tant il y a au point de vue de cette région cérébrale similitude entre les deux types. Nous sommes donc en droit d'exprimer cette similitude, en appelant du même nom de *deutocérébron* le deuxième segment cérébral, qu'il s'agisse d'un Crustacé ou d'un Insecte."

In favor of contrary views little can be said. "Arguments drawn from the absence or presence of either pair of antennæ in the higher Crustacea are not convincing, as there is great variation in the degree of development of their appendages in different groups" (Claypole, '98, pp. 265-266). Thus, in some Amphipods, the antennules are short, and in certain Isopods, extremely reduced. On the other hand, as Claypole notes, it is suggestive that in the generalized genus *Apus*, the first antennæ are constant and the second variable or absent.

The fact that the antennules of decapod Crustacea cannot be called "post-oral" in origin, is not as significant as it may appear to be. The antennules originate at the side of the labrum (Reichenbach, '86), nearly post-orally, and migrate forward. In view of all other fundamental correspondences between hexapod antennæ and crustacean antennules, the trifling difference in original position may be ignored, especially as the organs in question are eminently migratory.

I believe, therefore, that the deutocerebrum of Apterygota, representing the second somite, is homologous with that of Orthoptera and other insects.

Premandibular Appendages.

The little-known "premandibular" or "intercalary" appendages are important as bearing upon the larger and much-disputed question of the segmentation of the head.

In *Anurida*, they are visible in Stages 1 and 2 only, as slight thickenings of the germ band, which are often ill defined in outline and hardly deserve the name of appendages. In fact, their demonstration is largely a matter of technique. I dissected over thirty germ bands for this purpose, stained them variously, and mounted them temporarily in weak glycerine, without finding more than suggestions of the intercalary appendages. At this point, Miss Claypole most kindly sent me some preparations which were a little clearer than any I had made. These I imitated by staining with Delafield's hæmatoxylin, decolorizing with acid alcohol and mounting without pressure in xylol balsam. If care is taken in decolorizing, a condition may be obtained in which all of the germ band between the antennæ and mandibles has lost color excepting a rather vague patch on either side, usually not as distinct as in Plate 2, Figure 8^a, *app. pr'md.* These patches are so slightly, if at all, elevated that they are not distinguishable with certainty in transverse or sagittal sections of the germ band. In good preparations, the lateral boundary of either appendage is indicated by a curving row of ectodermal nuclei, and this resemblance to the other paired fundaments is further shown in the presence of an imperfectly developed core of mesodermal nuclei (Figure 8^a, *ms'drm.*).

Wheeler and Claypole have represented the appendages much smaller than I have, and appear to have figured the mesodermal core only. In none of Miss Claypole's slides are the appendages outlined as sharply as in the preparation from which my Figure 8^a was made. In glycerine the yolk granules interfere with proper observation, but in balsam this disadvantage is removed.

Although the appendages are extremely rudimentary, the evidence they furnish of the presence of an intercalary segment is reinforced by the condition of the nervous system, for there is at Stage 5 a small neuromere (Plate 4, Figure 28, *tri'ceb.*), which, from its relation to the remaining cephalic neuromeres, must be regarded as belonging to the premandibular segment. It ultimately fuses with the deutocerebrum to form a part of the supræesophageal ganglion.

Viallanes first called attention to the tritocerebral segment of insects and Crustacea; he was afterwards supported by Wheeler, who found that it bore a pair of appendages in *Anurida*; thus Wheeler ('93, p. 57, Figure VI.) discovered the intercalary appendages in this species, and indicated their obscurity by representing them by broken circles. Claypole ('98, p. 263, Plate XXIII., Figures 40, 47) also observed the appendages, but erroneously inferred that they became modified

to form the sides of the face,—a view which I shall discuss presently.

A somewhat similar pair of appendages in the embryo of *Apis* was long ago observed by Bütschli ('70), and a few years later by Grassi ('85) also; but Packard ('98, p. 52, Figure 35) questions whether these belong to the category of segmental appendages.

Heymons ('95^b, Taf. I., Figur 5) also has recognized the "Vorkiefersegment" in Orthoptera. He says ('95^a, p. 16): "Letzteres [Vorkiefersegment] kommt, wie schon gesagt, überhaupt nur in ganz rudimentärer Weise zur Anlage. Extremitäten treten an ihm nicht mehr auf. Sein Ganglion rückt nach vorn und geht in die Formation des Gehirns ein. Bei dieser Gelegenheit werden zugleich auch die äusserlich wahrnehmbaren Spuren des Vorkiefersegments verwischt. Selbst im Innen liegen die Verhältnisse nicht viel günstiger. Das Mesoderm des Vorkiefersegments bildet nämlich bei den Orthopteren ein eigenartiges Organ, den sogenannten Suboesophagealkörper, welches ebenfalls nur eine provisorische Bedeutung besitzt und später zu Grunde geht."

The same author ('97^a, p. 590, Figur II.; Taf. XXX., Figuren 17, 20), referring to the embryo of *Lepisma*, writes (p. 591), "Genau auf der Grenze zwischen dem verbreiterten vorderen Kopfabschnitt und dem darauf folgenden verjüngten Körpertheil zeigen sich ferner zwei, allerdings nur schwach markirte, laterale Vordickungen (*Trc.*). Dieselben kennzeichnen die Region des rudimentären Vorkiefer- (Intercalar) Segmentes. An diesen Segmente kommen während der Entwicklung von *Lepisma* Extremitäten nicht zur Ausbildung." This nearly agrees with the condition in Anurida.

Uzel records distinct intercalary appendages for Campodea in his preliminary paper ('97^b, p. 232), and in his final work ('98, p. 26) says: "Sehen wir auf dem sogenannten Intercalarsegmente (Vorkiefersegmente), das sehr deutlich entwickelt ist, jederseits eine kleine Erhöhung auftreten (*int.*), welche als die Extremitätenanlagen dieses Segmentes zu deuten sind." (p. 37.) "Die Extremitäten dieses Segmentes werden bei Campodea in Form zweier Höcker angelegt, welche sich, wie wir voraussenden wollen, bis in das geschlechtereife Alter erhalten, und hier als Bestandtheile der ausgebildeten Mundwerkzeuge fungieren (der einzige bekannte Fall unter dem Insecten), indem aus ihnen kleine, praeoral gelegene, beiderseits an der Wurzel der Oberlippe befindliche Lappen (die Intercalarlappen, Taf. VI., Fig. 85, *int.*) entstehen. Bei *Lepisma* sind keine Extremitätenanlagen auf dem Intercalarsegmente vorhanden." . . . "Unter den Myriopoden wurden von Zograf bei

den Embryonen von *Geophilus* ziemlich weit hinter dem Munde und dicht vor den Anlagen der Mandibeln zwei ansehnliche Höcker beschrieben und abgebildet, welche wahrscheinlich den Höckern auf dem Intercalarsegmente von *Campodea* homolog sind. Sie werden nach dem erwähnten Autor immer kleiner und kleiner und sollen endlich ganz verschwinden."

In *Anurida* the intercalary thickenings become involved in the folds which form the sides of the face, as I shall describe, but I believe they are not, as Miss Claypole held, the fundaments of those folds.

In *Tomocerus* and *Orchesella* (Folsom, '99, p. 14, Plate 2, Figure 9) I have found that "at either end of the [labral] hinge . . . the cuticula is swollen into a conspicuous chitinous lobe, which projects into the pharynx to fit against a corresponding prominence of the mandible," etc. As these lobes in the adult occupy precisely the same positions as those of *Campodea* (Uzel, '98, Taf. VI., Figur 85, *int.*), I believe them to be intercalary appendages. In *Anurida* no such lobes exist.

In Chilopods, two pairs of antennal fundaments appear (Heymons, '97^b, p. 4, Figur 1, *Scolopendra*), and the second, which alone become functional, are equivalent in position to the intercalary appendages of *Apterygota* as well as the antennæ of *Diplopods* (cf. Heymons, '97^b, p. 7, Figur 2, *Glomeris*).

The equivalence of the tritocerebrum in *Hexapoda* and *Crustacea* was first shown in detail by Viallanes. His account ('87, pp. 105-108) is too long to be quoted in full, but he concludes: "Les deux lobes constitutifs du tritocérébron de l'Insecte, et que j'ai désignés sous le nom de lobes tritocérébraux, représentent exactement les deux ganglions œsophagiens du Crustacé; ils donnent naissance aux mêmes racines nerveuses, ils sont, comme ces derniers, unis *au-dessous* de l'œsophage par la commissure transverse de l'anneau œsophagien."

Many authors (Korschelt und Heider, '90-93, p. 906) agree in homologizing the antennæ of *Hexapoda*, innervated from the deutocerebrum, with the first antennæ of *Crustacea*; also in homologizing the mandibles of both groups. Therefore only the intervening appendages of the tritocerebrum remain to represent the second antennæ of *Crustacea*.

An intercalary segment, then, is to be recognized among *Pterygota*, at least in the more generalized forms, and especially among the primitive *Apterygota*, and in the latter group it may bear rudimentary appendages, even in the adult. The intercalary segment is to be regarded as equivalent in morphological value to any primary head-segment, — especially because it bears a primitive ganglion, — and it constitutes the

third head somite. The tritocerebrum of Hexapoda is equivalent to that of decapod Crustacea, and the intercalary appendages of the former are homologous with the second antennæ of the latter, and probably with the antennæ of Chilopoda and Diplopoda.

Mandibles.

The fundamentals of the mandibles appear in Stage 1 (Plate 1, Figure 1, *md.*; Plate 2, Figure 8) as a pair of sub-hemispherical papillæ behind the antennæ, and considerably nearer than they to the median plane. At Stage 2 (Plate 1, Figure 2, *md.*) they are longer and bluntly conical; but at Stage 3 (Plate 1, Figure 3; Plate 2, Figure 9, *md.*) in lateral aspect they appear shorter than before, because the base is covered by a lateral fold of the germ band (Figure 9, *pli. or.*). Sections through the mandibles transverse to the germ band (Plate 3, Figure 16) show that they are low broad ectodermal evaginations containing mesoderm. In Stage 4 (Plate 1, Figure 4; Plate 3, Figure 19, *md.*) the mandibles, although they have become long and cylindrical, are largely covered by the lateral folds (*pli. or.*) which have grown more rapidly than they; and in the following stage (Plate 1, Figure 5; Plate 3, Figure 20, *md.*), though still nearly perpendicular to the germ band, they are almost completely covered laterally by the folds. The mutual relations of mandibles and folds are shown in transections of the germ band (Plate 4, Figure 23), in which it may also be seen that the mandibles (*md.*) are swollen at their ends, their lateral surfaces conforming to the adjacent surfaces of the folds (*pli. or.*). The long axes of the mandibles converge at their bases toward the median plane, and it is noteworthy that the lateral surface of each mandible is distinctly longer than the mesal surface (Figure 23, *md.*)—a foreshadowing of the oblique orifice of the finished organ.

At Stage 7 (Plate 2, Figure 7; Plate 4, Figure 24, *md.*) the mandibles, now wholly covered by the lateral folds (*pli. or.*), are much longer and still conical; they are shorter and much more slender than the underlying first maxillæ;—and instead of being perpendicular to the germ band, they have now swung forward through an angle of almost ninety degrees; moreover, they converge in front toward the median plane, as do the first maxillæ (Plate 5, Figure 29). In this stage the mandibular muscles are individually distinguishable (Figure 32), and the anterior extremity of the mandible bears several minute lobes (Figure 32), each consisting of a single hypodermal cell. In the next (8th) stage the free

end continues to bend toward the median plane until the apices of both mandibles meet. The terminal unicellular lobes become multicellular and secrete the incisive teeth (Plate 6, Figure 37 *de. i'cis.*), of which there are finally five principal ones on the right and six on the left mandible. Although the "head" of the completed organ is almost solid chitin (Plate 6, Figure 37), there are five canals, one penetrating the base of each tooth; the hypodermal cells have, however, receded from the "head."

The extreme basal end of the finished mandible is prolonged as a chitinous, conical projection (Plate 6, Figure 36, *cdx.*), which, as in *Orchesella*, is let into a concave chitinous piece that I have called the stirrup (*sta.*), from which it may be withdrawn when the mandibles are protruded. This projection, or pivot, arises in Stage 7 (Plate 5, Figure 32, *cdx.*) as a hypodermal evagination of the mandibular fundament, and simultaneously the chitinous stirrup (*sta.*) is formed in a transverse, superficial groove of the hypodermis lining the pharyngeal pocket in which the mandible lies. In *Orchesella* the lateral end of the stirrup unites with the external cuticula of the skull after traversing two layers of hypodermis: first, the layer lining the mandibular pocket, and second, the superficial layer of the head; in *Anurida*, however, I have found no such union between stirrup and skull. The body of the mandible is simply a modified cone, and hence in sections across this region appears as a complete chitinous ring (Plate 7, Figures 44, 45, *md.*).

In *Anurida* no trace of a mandibular palpus exists at any stage, and, unlike *Orchesella*, no molar surface is differentiated; the latter fact is correlated with the character of the food: *Orchesella* feeds upon lignified vegetable substances, *Anurida* upon the soft tissues of the mollusk *Littorina littoria*. In further correlation with diet, the powerful rotators, or grinding muscles, of *Orchesella* are not represented in *Anurida*.

Several writers on *Collembola* have already given surface views of the mandibular fundaments at early stages, although none have traced their development. I refer especially to Lemoine ('83, *Smynturus*) and Wheeler ('93, p. 57, Figure VI., *Anurida*). Packard ('71, p. 17; Plate 3, Figure 13) evidently overlooked the mandibular fundaments of *Isotoma*, and what he regarded as mandibles are clearly, from their position, the first maxillæ. Ryder ('86) made the same mistake.

Claypole ('98, Plate XXIII.) gives several figures of the mandibular fundaments of *Anurida maritima* before much differentiation has occurred, and Uzel ('98, Taf. VI., Figur 87) represents the fundaments in *Macrotoma* (*Tomocerus*) at a stage equivalent to that of my Figure

21. He also gives a figure (Taf. V., Figur 64) supporting his statement (p. 22) concerning the appearance of the mandibular segments: "Ausserdem [collection of entoderm cells, etc.] bemerkt man zwei Paar dunkler Stelle, welche an den Ecken eines gedachten Quadrats sich befinden. Das dem Dorsalorgane genäherte Paar dieser Blastodermverdickungen (*kl.*) sind die getrennten Anlagen der Kopflappen, das zweite Paar (*mds.*) stellt die getrennten Anlagen des Mandibularsegmentes vor." The eggs of *Anurida* at my disposal were either too old or too young to show the condition here described by Uzel, although I did find a stage in which three pairs of fundaments were present, the third pair being the first maxillæ. The mandibles probably follow the procephalic lobes in appearance, as I have found all the stages necessary to indicate that the remaining paired appendages, except those of the superlinguæ, as I shall term them, appear successively from in front backward.

Campodea is structurally nearest to the Collembola, and, thanks to Uzel ('98, Taf. III., Figuren 35, 36; Taf. VI., Figuren 77-85), something is known concerning the development of its mouth-parts. The mandibular fundaments of Campodea are simple papillæ, as in Collembola; this simplicity distinguishes the Apterygota from the most generalized Pterygota, the Orthoptera, in which the fundaments are sometimes lobed.

The finished mandible of Campodea is strikingly like that of the Collembola, and is, moreover, of great morphological interest, because the structural correspondence of the mandible with the maxilla of hexapods — obscure in almost all other insects — is here a matter of direct observation, not merely one of inference. The mandible of Campodea (Meinert, '65, Taf. XIV., Figuren 15, 16; Nassonow, '87, p. 33, Figur 27) consists of a hollow fulcrum (*stipes*) and a head, which is separated from the fulcrum by a transverse suture. The head is composed of two parts, — a large, toothed, immovable, outer lobe or *galea*, and a smaller, fringed, movable, inner lobe, representing the *lacinia*.

Accepting the homologies with the first maxillæ implied in these terms, the palpus remains to be accounted for. A mandibular palpus has never been found among adult insects, — the evidence given for one by Hollis ('72) being quite vague and inadequate. Although the detailed development of the mouth-parts of Campodea has never been followed, it is in this most generalized insect that one may most hopefully look for a trace of a mandibular palpus, and we may safely predict that, if found, it will be a lateral, distal lobe of the stipal region, just as it is in the maxillæ of all insects.

The agreement between the finished mandibles of *Campodea* and *Japyx*, on the one hand, and *Collembola*, as represented by *Anurida* and *Orchesella*, on the other hand, is remarkably close. In both groups the mandible is hollow, has an oblique basal opening, which is large in *Campodea*, and, instead of an ordinary articulation, a free basal pivot, which is peculiar to the *Apterygota*. The homologies extend further, for I find that the similar and complicated movements of the mandibles are actually effected by muscles which are probably homologous in the two groups. The equivalence of certain muscles in *Campodea*, as represented by Meinert ('65, Taf. XIV., Figure 15) with others figured by myself for *Orchesella* (Folsom, '99, Plate 2, Figures 14, 15) may be expressed in tabular form as follows:—

<i>Campodea</i> (Meinert).		<i>Orchesella</i> (Folsom).	
Muscle <i>C</i> (distal)	corresponds with	<i>9. add.</i>	
" <i>C</i> (proximal)	" "	<i>1. rot. l.</i>	
" <i>D</i>	" "	<i>5. pr't. l. and 6. pr't. ms.</i>	
" <i>E</i>	" "	<i>3. ret. rot. and 4. ret., or else 7. rot.</i>	<i>and 8. rot.</i>

The incompleteness of Meinert's figure prevents as exact a comparison as is desirable.

Japyx is nearest *Campodea* in structure, and the mandibles of *Japyx*, which have been described and figured by Meinert ('65), Grassi ('86^b), and v. Stummer-Traunfels ('91), are essentially like those of *Campodea*, but lack the articulated lacinial lobe, there being a lacinial region, however, which (Grassi, '86^b, Taf. II., Figura 14) is separated by a transverse line from the fulcrum. The muscles of *Japyx* agree with those of *Campodea*, and it is to be noted that the adductors originate upon a median chitinous plate, or tentorium, just as in *Collembola*, but not as in *Orthoptera*. The muscle *f* of Meinert ('65, Taf. XIV., Figuren 5, 15) has no homologue, it should be said, among the mandibular muscles of *Orchesella*, and I should be disposed to regard it as an adductor of the head of the first maxilla, had not v. Stummer-Traunfels ('91, Taf. I., Figuren 1, 3) figured the tendon of the same muscle in *Campodea* and *Japyx* going to the mandible. This author ('91, p. 220) erroneously states that the adductors of *Collembola*, *Campodea*, and *Japyx* are attached to the "Stützapparate," by which he means the lingual stalks (Plate 6, Figure 38, *pd.*¹); these, however, are quite distinct from the tentorium, which he apparently overlooked.

Nearly allied to the entognathous genera *Campodea* and *Japyx* are the ectognathous genera *Lepisma* and *Machilis*. In *Lepisma* the early

development of the mandibles, as shown by Heymons ('97^a, Taf. XXX., Figuren 13, 15, 17, 20), is simple, and agrees with that of Anurida and Campodea. The finished mandible of *Machilis* (Oudemans, '88, Plate II., Figuren 25, 26), especially, recalls that of Campodea and Collembola by its elongated hollow fulcrum, oblique aperture, basal pivot, distinct head, and (as in *Orchesella*) well-developed molar surface; moreover, the adductors originate on a tentorium and are inserted within the mandibles (Oudemans, '88, Taf. 1, Figur 19; Wood-Mason, '79, p. 148, Figure 1). Wood-Mason named the apex of the mandible "exopodite" and the molar lobe "endopodite," but upon superficial grounds, if one may judge from the evidence of embryology. Both lobes may together represent the endopodite; but the exopodite, or palpus, is unrepresented in the mandible, and it is a secondary lobe of the primary, or stipes, fundament, in the first and second maxillæ. Wood-Mason ('79) pointed out many interesting similarities which *Machilis* and *Lepisma* bear to the most generalized Orthopteran family, the Blattidæ, and remarked (p. 149), concerning the pivot of *Machilis*, that "the posterior ball-shaped condyle of mandibulated insects, clearly foreshadowed in the myriapod, is here fully formed and provided with a distinct neck."

The mandibles of *Lepisma*, however, more closely approach the Orthopteran type in being compact (v. Stummer-Traunfels, '91, Taf. II., Figuren 5, 6) and partly solidified, and in having broad incisive teeth, a molar surface like that of Orthoptera, and broadly attached adductors. The muscles are said by Oudemans ('88, p. 187) to resemble those of *Machilis*. V. Stummer-Traunfels represents the adductors only, and it may well be that the muscles are really much fewer than in Campodea and Collembola, such a reduction in number, if it occurs, being an approach to the Orthopteran type, in which but two mandibular muscles exist — a stout adductor and a slender abductor.

As to the development of the mandibles in Orthoptera, very little has been published. Ayers ('84, p. 241, Plate 18, Figures 20–22) says that in *Ecanthus* "the three oral appendages are trilobed; the lobation is most prominent in the second maxillary and least in the mandibular appendage. The primitive appendage is first divided into two lobes, and the inner of these becomes secondarily divided into two." The three lobes doubtless represent palpus, galea, and lacinia. Korotneff ('85, Taf. XXIX., Figure 6) figures lobed mandibular fundaments for *Grylotalpa*. In other Orthoptera such lobation has not been recorded. In *Blatta*, according to Wheeler ('89, p. 348), "There are apparently no traces of lobation in the mandibles." Packard ('83^a, p. 279) says,

"The mandibles [of Caloptenus] remain single-lobed," and both Wheeler ('93) and Heymons ('95^b) represent them as simple papillæ in all families of Orthoptera. It may at least be said, however, that the mandibles of Collembola and Thysanura are certainly homologous in their entirety with those of Orthoptera, and hence of all other insects.

It is an interesting fact that Heymons ('96, Taf. II., Figur 29) distinctly represents mandibular palpi for the larva of Ephemera, — a rare condition; indeed, Packard ('98, p. 61) terms this appendage of nymphal Ephemerids a "lacinia-like" process, although Heymons states (p. 21) that it is lateral in position, and so figures it.

What embryological evidence there is, then, confirms the view based upon anatomical data, that "the mandibles are primarily three-lobed appendages like the maxillæ" (Packard, '98, p. 61).

Turning now to the Myriopoda, the Symphyla, represented by the single genus Scolopendrella, show marked affinities with Campodea, as is well known. I wish here to emphasize especially the correspondences between the mouth-parts of the two genera, which have never been carefully compared in these respects.

Latzel ('84, p. 8, Taf. I., Figur 5) describes the mandibles of Scolopendrella as follows: "Die Oberkiefer bestehen jederseits aus einer fast horizontal gelagerten, trapezoidalen Chitinplatte, welche am End- oder Kaurande durch eine mittlere Einbuchtung in zwei Partien abgetheilt erscheint, von denen die vordere in vier kräftige, die hintere in vier bis fünf kleinere Zähnchen eingeschnitten ist. Eingelenkt sind diese Kieferplatten mit dem hinteren und äusseren Eck in eine zwischen Kopfdecke und Unterseite eingelagerte seitliche Lamina, welche einige Aehnlichkeit hat mit der Wange der Insecten und die von Menge als Theil (Stamm) der Oberkiefer aufgefasst wird. Am inneren Hintereck jeder der beiden Oberkieferplatten entspringt eine sehr kräftige Sehne, die in eine beträchtliche Anzahl von Muskelbündeln ausläuft, welche sich unten am Kopfrahmen inseriren."

The mandibles of Scolopendrella therefore resemble those of Campodea rather than those of any other insect, in that they are hollow, with a basal (stipal) part articulated to the skull, and a head separated transversely from the fulcrum. The head consists of two primary lobes (galea and lacinia) as in Campodea, but both are movable by muscles, whereas in Campodea the lacinia alone is articulated, and even this no longer has muscular attachments. The tendon and muscles which move the lacinia of Scolopendrella are exactly similar in position and function to the "chitinous rod" and muscles which adduct the head of the first

maxilla of Orchesella, Japyx (Meinert, '65, Taf. XIV., Figur 8) and doubtless Campodea. More important, however, is the fact that the tendon of Scolopendrella is comparable with the mandibular retractor (cf. Latzel, '84, Taf. 1, Figur 5, ϵ , and Meinert, '65, Taf. XIV., Figuren 5, 15, *f.*, *flexor*) of Campodea and Japyx, and may be homologous with it. It can be easily understood that, if the terminal lobes in Scolopendrella became immovable by solidification in the mandible, the adductors of those lobes would then serve as retractors of the entire mandible, as in Campodea and Japyx.

Grassi ('86^a, pp. 15-16, Tav. II., Figure 2, 5) supplements Latzel's account of Scolopendrella by saying that no true cardo is present, and that the mandible is capable of lateral movements only.

Packard ('83^b, p. 198) says, "The so-called mandibles of the Myriopods are the morphological equivalents of those of insects, but structurally they are not homologous with them, but rather resemble the lacinia of the hexapodous maxilla." With the last assertion I do not agree. The mandibles of the more generalized Diplopods are in detail strikingly like those of Scolopendrella (Latzel, '84, Taf. I., Figur 5); for example, those of Polyzonium (Latzel, '84, Taf. XVI., Figur 203), in which the only fundamental difference is the presence of a cardo in Polyzonium, the stipes, galea, lacinia, and tendon being essentially as in Scolopendrella. The mandible, or protomala (Metschnikoff, '75), of Polyzonium does, indeed, resemble, not the lacinia, but the entire first maxilla of Thysanura and Collembola. The similarity, however, should not be mistaken for homology; it rather serves to emphasize the structural agreement of mandibles and maxillæ, — an agreement which gradually becomes obscure in the insect series through the progressive solidification of the mandible, but may nevertheless be traced, as I have shown, from Diplopoda and Symphyla, through Campodea and Japyx, Machilis and Lepisma, to the more generalized Orthoptera; thus the differences between the mandibles of Diplopods and Insects are not so great as Packard has affirmed ('98, p. 12).

The most that is known about the development of Diplopod mouth-parts we owe to Metschnikoff ('74), who represents only two pairs of oral fundaments, designated "mandibles" and "labium." Although this conclusion is also reached by vom Rath ('86), I would not infer with Packard ('83^b, p. 199) that there can be only two pairs of oral appendages, but would suggest that embryological studies upon the mouth-parts of other Diplopoda may, perhaps, show more.

The mandibles, or protomalæ, of Chilopoda are generally recognized as

equivalent to those of Chilognatha, and, indeed, to the mandibles of Hexapoda and Crustacea. In the mandibles of Scolopendra (Meinert, '83, Taf. II., Figur 9), for example, there can be recognized cardo and stipes, a distinct head with galeal and lacinial lobes, and even muscles exactly comparable with the adductors and retractors of the mandible in Campodea and Japyx. The affinities of the Chilopods are, however, with the Diplopods, — from the stem-form of which they may have developed, — rather than with the Campodeidæ. Although Packard ('98, p. 15) states, "In the Chilopoda also the parts of the head, except the epicranium, are not homologous with those of insects, neither are the mouth-parts," there is really much indirect evidence of homology with the mouth-parts of insects through Diplopoda, Symphyla, and Thysanura, as is indicated above.

The mandibles of Crustacea have usually been considered homologous with those of insects. In Malacostraca (Reichenbach, '86), as in insects, the mandibular fundamentals are a pair of appendages of the fourth primitive segment. In insects the exopodite (palpus) is absent, but in such generalized groups as Campodea and certain Ephemeridæ, a "lacinia mobilis" is present; in Malacostraca the palpus is present, and likewise, according to Hansen, a similar lacinia is found in the groups Mysida, Cumacea, Isopoda, and Amphipoda, although not in Decapoda.

Among insects, the Thysanura most nearly approach Crustacea. Hansen ('93, pp. 205–206) says of *Machilis*: "Die Mandibeln sind homolog mit denen der Malacostraken; in Form sind sie denen der Cumaceen ähnlich, mit einer gut entwickelten, fast cylindrischen Pars molaris, doch ohne Lacinia mobilis; in Einlenkung und Musculatur stimmen sie erstaunend überein mit z. B. *Diastylis* und *Nebalia*." Referring to Campodea, Japyx, and Collembola, he remarks (pp. 208–209), "Die Musculatur der Mandibeln ist noch mehr der Crustaceen ähnlich als der Musculatur der *Machilis*. Vergleiche Meinert's Figur von *Japyx* mit meiner Figur von *Diastylis Goodsiri* in 'Dijmphna-Togtet' (ich habe nur die drei grössten Muskeln oder ihre Sehnen wiedergegeben) oder mit Sars' Figur von *Diastylis sculpta*, und man wird betroffen von der erstaunlichen Uebereinstimmung in Form und Richtung der Muskeln und der grossen medianen Muskelplatte."

In conclusion, the mandibles of Apterygota agree in development with those of Orthoptera, but show no trace of lobation except in Campodea, the most primitive form. The mandibles and maxillæ are homodynamic, and the former are homologous with the mandibles of Scolopendrella, Crustacea, and probably Diplopoda.

Lingua and Superlinguæ.

Not until Stage 3 are the fundamentals of the superlinguæ ("para-glossæ" of some authors) observed ; then a ventral aspect of the germ band (Plate 3, Figure 11) reveals two small papillæ (*su'lng.*) between the mandibles with their centres slightly more anterior than those of the mandibles. Although each small papilla is adjacent or contiguous to the mandibular fundament of the same side, it originates quite independently ; in other words, it is not the inner branch of a biramous appendage, but a distinct ectodermal evagination, as transections of the germ band (Plate 4, Figure 23, *su'lng.*) prove.

At Stage 4 (Plate 3, Fig. 12, *su'lng.*) the superlingual fundamentals are longer and stouter than before, and have moved back slightly in relation to the mandibles until nearly opposite them.

At Stage 5 the centres of the superlinguæ (Plate 3, Figure 21, *su' lng.*) are behind those of the mandibles, and in cross-sections (Plate 4, Figure 23) the former structures are seen to have exceeded the latter in rate of elongation. The long axes of the superlinguæ now diverge anteriorly from the median plane and the apices are partly under the mandibles, as in the adult, though the bases retain nearly their original positions in relation to the bases of the mandibles. During this stage is seen the first trace of the lingua (the "ligula," or "hypopharynx" of some authors), as a slight, median, unpaired, oval, ectodermal evagination (Plate 3, Figure 21, *lng.*) between the first maxillæ. This is the last of the oral fundamentals to make its appearance.

In Stages 6 and 7 the lingua becomes longer and stouter, and, as seen in a ventral view of the germ band (Plate 5, Figure 30, *lng.*), its cross-section is rounded-triangular with its anterior median angle intruding between the two superlinguæ. Sections show that the lingua and superlinguæ have swung forward from their former positions at right angles to the germ band, and that the lingual and superlingual cavities are separately confluent with the general body cavity of the head. In the region of confluence a common cavity — a prolongation of the body cavity — is formed by a median evagination of the germ band itself. In Apterygota the superlinguæ, however, never become appendages of the lingua.

In ventral aspect, the lingua at Stage 7 (Plate 4, Figure 27 ; Plate 5, Figure 29) is cuneate with rounded apex, and, a little later (Plate 4, Figure 25, *lng.*) becomes constricted distally, forming a terminal lobe.

In Stage 8 the lateral surfaces (Plate 5, Figure 34) become concave,

to correspond with the adjacent convex surfaces of the first maxillæ, as in the adult (Plate 7, Figures 44, 45, *cht.*), and each ventro-lateral edge extends under the neighboring maxilla; in addition, the apex of the lingua becomes separated into two lateral lobes by a median sinus, and the dorsal surface invaginates to form a median longitudinal groove (Plate 7, Figure 42, *sul.*); this lobed condition, however, is quite secondary in origin.

The lingua is thickly chitinized, and the hypodermal cells persist in the mature organ. The superlinguæ, on the contrary, are but thinly chitinized and at maturity contain no distinct hypodermis cells, except basally, although a complete layer of cells exists in Stage 8. In this stage (8) the superlinguæ become triangular in cross-section, as in the adult (Plate 7, Figure 44). Partly on account of the divergence of the superlinguæ in front, but principally owing to the convergence of the mandibles and maxillæ, the attenuated distal part of each superlingua becomes situated between the apices of the mandible and the first maxilla of the same side (Figure 44), and the superlinguæ conform to the adjacent surfaces of the maxillæ.

The most interesting lingual structures are the two basal stalks (Plate 6, Figure 38, *pd.*'), each of which articulates with the cardo of the same side and also furnishes a firm origin for the adductors and retractors of the first maxilla, as in *Orchesella* (Folsom, '99, Plate 3, Figure 21). The development of these stalks has never been described. Although difficult to comprehend with a knowledge of the finished condition only, it is simpler than might be expected. The key to the understanding of its origin is the fact that each chitinous stalk is formed in a groove which is but a longitudinal evagination of the maxillary pocket, and follows the mesal surface of the first maxilla back to the cardo. The base of the lingual fundament is at *ba.* in Figure 30 (Plate 5), and that of the maxilla at *ba.*'; consequently the stalk is developed in a superficial groove of the germ band itself — that part of the germ band connecting the base of the lingua with the extreme base of the maxilla. In ventral aspect at Stage 7 (Plate 5, Figure 29, *pd.*'), the continuity of the stalk along the surface of the maxillary pocket is evident. Dorsal to the stalk, of course, the base of the maxilla is connected with the head, but under the connecting region passes the stalk.

I must now explain how maxillary muscles become attached to the stalk in spite of the fact that the latter is a superficial formation of the hypodermis. This may be learned from transections at Stages 7 and 8, but also, and more easily, from good serial sections of an adult head,

such as are shown in Plate 7, Figures 46-50, which successively represent sections in more posterior planes.

Figure 46 shows the right maxilla (*mx.*¹) sectioned in front of its basal opening and lying free in its pharyngeal pocket; it also shows the stout, superficial chitinous stalk (*pd.*¹) in its hypodermal groove. Figure 47 represents the beginning of an evagination (*pli.*) of the dorsal wall of the pocket, which grows down between the maxilla and chitinous stalk. Passing back, the intruding hypodermal fold expands, as in Figures 48 and 49 (*pli.*), until it almost encloses the stalk. Finally, in the region of the maxillary aperture (Figure 50), and on account of its obliquity, adductor muscles (*mu.*) are enabled to pass directly from the inner wall of the stipes to the chitinous stalk (*pd.*¹). They are not attached directly to the stalk, but to an intervening cuticula (*cta.*); this, however, amounts to the same thing, because the cuticula and stalk become fused together at about Stage 7, and hardened into a single piece. It should be stated that the hypodermal cells which formed the intervening cuticula, as well as those which formed the stipes, are seen in embryological life only; they disappear at the origin and insertion of muscles.

At Stage 7 the end of each stalk is already feebly fused with the end of the cardo to form an articulation (compare Plate 4, Figure 25, with Plate 6, Figure 38, *etc.*). This is a simple process, as both cardo and stipes are superficial and contiguous structures. In the adult *Orchesella* (Folsom, '99, Plate 2, Figure 10, *lig.*¹) a long ligament unites them, and I mentioned a distinct suture as possibly indicating the end-to-end union of two ligaments, which doubtless occurred.

The lingual stalks, then, are quite independent of the lingua in origin, except that they are thickened cuticular structures continuous with the lateral cuticula (Plate 7, Figure 45, *cht.*) of the lingua. When dissecting out the lingua at Stage 7, it frequently breaks away from the stalks at the sutures (*sut.*) shown in Plate 4, Figure 25; these sutures later become obliterated, however.

The lingual stalks of *Collembola* have been mentioned by several authors, for example, de Olfers ('62, p. 18) in several genera, Tullberg ('72, Taf. IV., Figur 17) in *Tomocerus*, and v. Stummer-Traunfels ('91, Taf. I. Figur 7) in *Tetradontophora*. I have seen them myself in all the more common genera; they undergo but little modification within the order.

As to the development of the lingua and superlinguæ in other insects, very little has been written. Packard ('71, p. 17), as quoted on page

128, did not find the "second maxillæ" (superlinguæ) in the embryo of *Isotoma*. Uzel alone has mentioned the embryonic lingua and superlinguæ of Apterygota. In Taf. VI. Fig. 87, he shows, in *Tomocerus*, three fundaments, which undoubtedly are these structures.

In *Campodea*, happily, Uzel describes with some detail the development of the "hypopharynx" ('98, p. 35): "Schon in jenem Stadium, bei welchem der Keimstreif sich in seinen mittleren Theilen in das Innere des Dotters einzusenken anfängt (Taf. IV. Figur 39), bemerken wir zwischen den beiden Anlagen der Mandibeln zwei einander sehr genäherte, ziemlich grosse, flache Platten (*hmd.*). Diese werden im nächsten Stadium, in dem die Umrollung des Keimstreifs vollendet ist, viel kleiner (Taf. VI. Figur 81, *hmd.*); dafür wölben sie sich jedoch bedeutend zu zwei spitzigen Höckern vor. Bald erscheint zwischen den Anlagen der ersten Maxillen eine unpaare, grosse, flache Platte (Figur 82, *hmx.*), vor der man eine kleinere sieht. Letztere befindet sich zwischen den beiden vorher beschriebenen spitzigen Höckern und gehört noch dem Mandibularsegmente an (Figure 83, *hmd.*!). Die unpaare, dem ersten Maxillarsegmente angehörende Platte schickt sich nun an, über die beiden Höcker und die zwischen denselben gelegene kleine Platte vorzuwachsen (Figur 84), und zwar etwa in der Zeit, zu welcher das Thier ausschlüpft." After hatching, continues Uzel ('98, p. 48), "Von den drei schon früher beschriebenen Höckern, die zwischen den beiden Anlagen der Mandibeln lagen, wird der mittlere immer kleiner. Bei dem erwachsenden Thiere haben sich die beiden seitlichen zu runden bewimperten Schuppen ungebildet, welche von Meinert ('67) als Paraglossæ bezeichnet worden sind. Zwischen denselben befindet sich der nun sehr klein gewordene mittlere Höcker als unbedeutendes Gebilde, welches die beiden seitlichen Schuppen verbindet. Die grössere, zwischen den beiden Anlagen der ersten Maxillen gelegene Platte hat sich auch in eine, aber entsprechend der mächtigeren Anlage, grössere Schuppe verwandelt und ist über die beiden Schuppen des Mandibularsegmentes erst beim geschlechtsreifen Thiere gänzlich vorgewachsen (Taf. VI. Figure 85, *hmx.*). Sie stellt Meinerts Ligula vor. Sowohl die von Meinert ('67) als Paraglossæ, als auch die von demselben als Ligula gedeuteten Theile sind, wie wir gesehen haben, ihrer Anlage nach als Hypopharynx aufzufassen."

The "hypopharynx" of *Campodea* is, then, undoubtedly homologous with the lingua and superlinguæ of *Anurida*, with the development of which it fundamentally agrees. In *Anurida*, however, as contrasted with *Campodea*, the superlingual fundaments do not show the early

decrease in size, and a small median lobe does not appear on the anterior surface of the lingua.

In the finished condition in *Campodea* (Meinert, '65, Taf. XIV. Figuren 17, 19) lingua and superlinguæ are simple but distinct lobes, and the small fourth lobe mentioned by Uzel persists. The lingual stalks are surprisingly like those of *Orchesella*; the articulation with the cardo Meinert did not show, but it has since been observed by v. Stummer-Traunfels.

The English translator of Meinert's paper is really responsible for the use of the terms "lingua" and "paraglossæ" in connection with this subject, and not Meinert himself; the latter writer applied only the Danish expressions "Tungen" and "Bitungens tvende Flige."

Von Stummer-Traunfels ('91, Taf. I. Figur 11) also represents the "Ligula," "Paraglossæ," and "Stützstücken" of *Campodea*. On page 121 I criticise this author for holding that the so-called maxillary palpus of *Collembola* belongs to the neighboring superlingua. The embryology shows that the delicate membrane connecting either palpus and superlingua is of quite subsidiary importance, being simply as much of the cuticula of the maxillary pocket as intervenes between the base of a superlingua and the adjacent maxilla, — in fact, only the anterior portion of the cuticula surrounding the tissues which attach the maxilla to the head.

Japyx agrees closely with *Campodea* in the structure of these organs (Meinert, '65, Taf. XIV. Figur 8; von Stummer-Traunfels, '91, Taf. I. Figur 10), and there is no doubt about the homology of the lingua, superlinguæ, and lingual stalks of Japyx with those of *Collembola*. In the words of v. Stummer-Traunfels ('91, p. 221), "Diese typische Form des Stützapparates und der Befestigung der Cardines an diesem findet sich bei *Campodea*, Japyx und den *Collembola* in beinahe identischer Weise ausgebildet." The author is mistaken ('91, p. 222), however, in saying that the mandibles are attached to the Stützapparate, apparently having overlooked the tentorium, which is quite another structure than his "Stützapparat."

Regarding *Lepisma*, Heymons ('97^a, p. 595) simply remarks: "Ich . . . bemerke nur, dass die Bildung der einzelnen Körpertheile, z. B. des Hypopharynx der Mundwerkzeuge, durchaus an den bei Orthopteren bekannten Typus anschliesst."

Machilis, also, has decided Orthopteran affinities, as Wood-Mason ('79) found, yet the mouth-parts of both *Lepisma* and *Machilis*, although ectognathous, as in Orthoptera, are constructed upon fundamentally the

same plan as those of the entognathous Apterygota. The similarity is evident in part from the following account of *Machilis* by Oudemans ('88, p. 186): "Letztere [Ligula], Figur 28 *Li*, reicht mit ihrem freien Ende ungefähr ebensoweit als die Unterlippe und wird durch zwei Chitinstäbchen gestützt, Figur 28 *S*, Figur 30 *S*. Mit der Ligula sind noch zwei Stücke, Figur 30 *P*, verbunden, die ich als Paraglossæ auffassen möchte. Sie sitzen an einer Chitinleiste, die sich auf der Dorsalseite der Ligula findet. Jede Paraglossa ist an ihrem freien Ende noch einigermaßen vertheilt (ich glaube in drei Lobi) und hat einen kleinen Vorsprung an ihrer Basis, Figur 30 *A*. Es scheint mir, dass die Paraglossæ ausserdem noch festsitzen an den Stützstückchen der Ligula, Figur 30 *S*."

. . . "Die Maxillarspitzen treffen einander mithin in dem Zwischenraum zwischen Ligula und Paraglossæ, Figur 21, die Mandibularspitzen zwischen Paraglossæ und Labrum."

Von Stummer-Traunfels ('91) repeats some of Oudemans' figures of *Machilis*.

In *Machilis*, I find that the first maxillæ articulate with the skull — no longer with the lingual stalks — and the stalks, although evident, are much reduced and apparently functionless. The salivary glands open, as in Orthoptera, under the base of the lingua.

In Orthoptera, the most generalized of the Pterygota, there is a well-developed hypopharynx, or lingua, which exactly corresponds in position with the lingua of Apterygota, being a median papilla between the bases of the first and second maxillæ. In *Periplaneta* (Miall and Denny, '86, p. 127, Figure 71) it is borne upon two chitinous stalks, clearly comparable with those in Apterygota. Looking for traces of superlinguæ in *Melanoplus femoratus*, I found them, as large dorso-lateral rounded lobes, intimately united, however, with the lingua. This union is already foreshadowed in *Machilis* and *Lepisma*. I also found — almost accidentally — two rudimentary, chitinous, divergent stalks, extending back into the head from the ventro-lateral regions of the base of the lingua. The significance of these facts is clear, although the meaning of the lingual appendages, which have apparently been overlooked or disregarded in most Orthoptera, could hardly have been ascertained without studying the less specialized Apterygota. In Packard's figure of *Anabrus* ('98, p. 73, Figure 71), also, the lingua and left superlingua are evident.

In the rare and singular *Hemimerus*, Hansen ('94, pp. 70-71, Plate 2, Figures 9, 10, *h*.) finds a "hypopharynx" and "maxillulæ," as well as

chitinous stalks, all of which distinctly are as in Collembola, Campodea, and Japyx, except that the superlinguæ of Hemimerus appear to be fused with the lingua. Figure 10 of Hansen bears a close resemblance to my Figure 27 of Anurida, although Hansen says (p. 87), "especially the structure of the mouth removes it [Hemimerus] very far [?] from the Thysanura and leads it to the Orthoptera."

In the young larva of Ephemera, Heymons ('96, p. 22, Taf. II. Figur 29) finds that "Der Hypopharynx entsteht . . . auf ähnliche Weise wie bei den Orthopteren. Auch an ihm findet eine Art Gliederung statt, dergestalt, dass von der eigentlichen Hauptmasse zwei laterale vordere Zapfen abgetrennt werden, die mit kleinen Härchen bedeckt sind, während der eigentliche Hypopharynx am Ende einen Besatz von feinen (Sinnes-) Borsten trägt." His figure of lingua and superlinguæ might fairly represent those structures of Anurida in Stage 7 (Plate 4, Figure 27). In the imago the mouth-parts are, of course, atrophied. In another Ephemerid nymph, Heptagenia, Vayssière ('82, pp. 113-114, Planche 5, Figure 46) found a highly developed lingua, or hypopharynx, fused with large lateral pieces [superlinguæ] and suggests that they indicate a distinct primitive segment, — a possibility which will be discussed later. He states (p. 106), "La langue ou hypopharynx . . . est assez développé chez tous les individus de la famille des Éphémérines, à l'exception du Prosopistoma, où il est très rudimentaire."

I shall not cite descriptions of the "hypopharynx" of additional insects, because I have nothing more to add, and the subject has been well treated of by Kolbe ('90, pp. 213-217, Figuren 126-134), Packard ('98, pp. 70-83, Figures 70-87), and others. Packard's comparative account, in particular, is most excellent and well illustrated. (In his Figure 69, by the way, the abbreviations *p.* and *hyp.* should be interchanged.) Briefly, the lingua is found in every order of insects, and although highly specialized in suctorial orders, retains, nevertheless, the same position and nearly the same relations to the salivary ducts that it does in the more generalized mandibulate orders which I have described. It is an interesting fact that in the Lepidopterous genus, Micropteryx, Walter ('85, Taf. XXIV. Figur 11) shows two hypopharyngeal stalks, readily comparable with those of Apterygota.

The superlinguæ — which, as I have shown, originate quite independently of the lingua in Apterygota, but become more or less united with it in Orthoptera and Ephemerida — should hereafter be recognized as morphologically important structures, and be searched for in even the most specialized haustellate orders as more or less intimate constituents

of the "hypopharynx," which term, then, may refer collectively to the lingua and "superlinguæ." The necessity for this new term, also brought out on page 132, will appear from the following synonymical table:—

AUTHOR.	APTERYGOTA.	HYPOPHARYNX.	
		<i>Lingua.</i>	<i>Superlinguæ.</i>
De Olfers, '62	Collembola	lingua	organa cochleariformia
Meinert, '65	Thysanura	tungen	bitungens tvende Flige
" (trans.), '67	Thysanura	lingua	paraglossæ
Packard, '71	Collembola	. . .	second maxillæ
Tullberg, '72	Collembola	lamina hypopharyngis inferior	laminae hypopharyngis superiores
Lubbock, '73	Collembola and Thysanura	ligula, lingua	second maxillæ
Grassi, '86	Thysanura	ligula	paraglossæ
Oudemans, '88	Thysanura	ligula	paraglossæ
V. Stummer-Traunfels, '91	Collembola and Thysanura	ligula	paraglossæ
Hansen, '93	Collembola and Thysanura	hypopharynx	maxillulæ
Heymons, '97	Lepisma	hypopharynx	
Uzel, '98	Collembola and Thysanura	hypopharynx	
Folsom, '99	Collembola	glossa	paraglossæ

Among Pterygota, the term "hypopharynx" of Savigny is fixed in application, although the compound nature of the organ is not generally known. Synonymous with "hypopharynx" are the following terms (see also Packard, '98, p. 71): lingua (Savigny, '16), ligula (Kirby and Spence, '28), langue ou languette (Dugès, '32), lingua (Westwood, '39, p. 9), tongue (Taschenberg, '79), hypopharynx (Dimmock, '81; Burgess, '80, and most others).

"Ligula," "glossa," and "paraglossæ" are terms established in Pterygota, but less fixed in the little-known Apterygota, and therefore more easily discarded in the latter group, as advised on pp. 132-133. "Maxillulæ" and "second maxillæ" as applied to superlinguæ are unfortunate because based upon unproved homological assumptions. The need for a new term, then, becomes evident. I have therefore suggested "*superlinguæ*."

In Scolopendrella authors have omitted to mention whether the hypopharynx is present or not.

Referring to Diplopoda, however, to which Scolopendrella is most nearly related, Packard ('98, p. 13) says, "The hypopharynx, our 'labiella' (Figure 6), with the supporting rods, or *stili linguales* (*sti. l.*), of Meinert, are of nearly the same shape as in some insects." Latzel (Taf. IX. Figur 104; Taf. VI. Figur 72) represents "ein Zwischenstück der

Zunge," for *Lysiopetalum* and *Craspedosoma* respectively, as well as two lateral lobes, or "Zungenlappen" (*lobi linguales*). These structures, although united with the gnathochilarium, are probably homologous with the separated *lingua* and *superlinguæ* of *Apterygota*, but, in the absence of the necessary embryological investigations, that is all that may be said.

In the *Chilopoda* no structure analogous to the *hypopharynx* appears to be known.

The "*superlinguæ*" of insects are homologous with the first *maxillæ* of *Crustacea*. In *Anurida* I have found (Plate 4, Figure 28, *su'lng.*) a distinct primitive ganglion — the fifth — for the *superlinguæ*, representing the fifth, or first maxillary, ganglion of decapod *Crustacea*. This ganglion is eventually incorporated with the subœsophageal ganglion, and no *superlingual* nerves develop. Moreover, the *superlinguæ* originate between the mandibles and so-called "first *maxillæ*" of *Anurida*. The *superlingual* fundaments, however, never become biramous — an *exopodite* or *palpus* does not appear — and are not segmented, like the *Crustacean* first *maxillæ*. In fact, they are much reduced structurally and functionally in *Apterygota*, and gradually reduced to disappearance in ascending the *Pterygote* scale.

Hansen ('93) regarded the *superlinguæ* — or "*maxillulæ*," as he termed them — from their position, as equivalent to the *Crustacean* first *maxillæ*, emphasizing the opinion of v. Stummer-Traunfels ('91) that the *superlinguæ* bore palpi. The latter argument cannot be used, however, because, as I show (p. 121), the palpi in question belong to the "first *maxillæ*."

The *lingua*, usually termed "*hypopharynx*" among insects, may easily be homologized with the *hypopharynx* of *Malacostraca*. It originates quite independently of the *superlinguæ* as a median, unpaired papilla, is not supplied with a primitive ganglion or distinct nerves, and can no more be regarded as a distinct segment than can the *labrum*. In *Orchesella* and *Anurida* it finally becomes distinctly bilobed by a median groove, but the bilateral condition is clearly secondary. Packard's evidence ('98, pp. 82-83) that the *hypopharynx* is "composed of, or supported by, two bilaterally symmetrical styles both in *Myriapods* and in insects" has little weight, in view of what I have found to be the development of these "*lingual stalks*."

The *hypopharynx* of insects, then, is a compound structure, the components of which originate independently. The median ventral *lingua*, like the *labrum*, does not represent a pair of appendages; the dorso-

lateral "superlinguæ," which have been usually overlooked or disregarded in Pterygote insects, represent a distinct though reduced somite, as confirmed by the presence of a primitive ganglion. The superlinguæ are homologous with the first maxillæ of Malacostraca, and are probably represented in Diplopoda.

The lingua of insects is homologous with the Crustacean hypopharynx and probably with the median constituent of the gnathochilarium of Diplopoda.

Maxillæ.

The fundaments of the "first maxillæ" appear next after those of the mandibles, and at Stage 1 (Plate 1, Figure 1; Plate 2, Figures 8, 8a, *mx.*¹) are a pair of small hemispherical papillæ, similar to those of the mandibles. At Stage 3 they are longer than the mandibles and must consequently have lengthened faster. As seen in transections of the germ band, the maxilla is at first a simple ectodermal evagination, apically rounded, but at Stage 3 (Plate 3, Figure 15) the apex is flattened, and a lateral lobe, the beginning of the palp, has appeared; this lobe is also seen in the ventral aspect of the germ band (Plate 3, Figure 11, *plp.*) as well as in the lateral views (Plate 2, Figures 9, 10). The posterior aspect of the left first maxilla when dissected out is given in Plate 3, Figure 17.

At Stage 4 (Plate 3, Figures 12, 19) the maxilla has elongated considerably and its base is covered by the lateral fold of the germ band (Plate 3, Figure 19, *pli. or.*), as already mentioned. In the following stage (Plate 3, Figures 20, 21, *mx.*¹) the maxilla and palpus, though longer, are more nearly concealed by the lateral fold. The form of the maxilla with its palpus at this stage is shown in Figure 22, which was drawn from a dissection; the base of the maxillary fundament is already oblique, precisely as described for the mandibles, and the first maxillæ have begun to converge toward the median plane. It is to be remembered that the palpus is here a secondary lobe of the primary fundament.

At Stage 7 (Plate 4, Figure 24; Plate 5, Figures 29, 30, *mx.*¹) the first maxillæ, now covered by the lateral folds, have swung forward through an angle of almost ninety degrees (Figure 24), like the mandibles. Claypole ('98, p. 263) states that "a flexure of the embryo begins that results in crowding the mouth-parts together to form a definite head," but such a purely mechanical interpretation will not serve, be-

cause the paired mouth-parts are still at right angles to the germ band long after involution has occurred (Stage 5, Figures 5, 20). During this stage (7) the first maxillæ are attenuated toward their free ends; a ventral view (Plate 5, Figure 29, *mx.*¹) shows their position in relation to the lingua, and the extent of their convergence toward each other. The maxilla is quite unattached to the pharyngeal pocket (Plate 7, Figures 44-50, *cav. buc.*) in which it lies, except where the margin of its basal aperture becomes confluent with the wall of the pocket (Figure 50); it has the form of a modified cone with an oblique, dorso-mesal, basal opening, as shown in transections (Figures 44-50, *mx.*¹). The parts named *stipes* and *chitinous rod* in my paper upon *Orchesella* are, as I have since found in that genus and in *Anurida*, distinguished simply by a greater deposition of chitin, and are connected above and below by delicate chitinated membranes, which I did not recognize until influenced by embryology to search for them. The "chitinous rod," then, is proved both by anatomy and development to be but a part of the *stipes*.

During this stage (7) certain important differentiations of the first maxillæ are observable, if those organs are dissected out. The articulation between *stipes* and *cardo* (Plate 6, Figure 38, *etc.*) appears superficially as a notch, and in frontal section as a less chitinated region, as might be expected; in a small hypodermal pocket is formed the stival projection (Figure 38, *prj.*) noticeable in the finished organ. The *cardo*, now transverse in position, was formerly the basal region of the lateral surface of the primary maxillary fundament, before the basal attachment became oblique. The articulation between the *cardo* and lingual stalk was described on page 112.

In this stage, too, the head of the maxilla becomes vaguely separated from the *stipes* by a constriction (Plate 5, Figure 29). Later, the constriction is more pronounced (Plate 4, Figure 25), and the apex of the head is fashioned into an acute curving lobe, — the fundament of the galea (Plate 4, Figure 26, *ga.*) or "aussere Lade." The "head" is lined with a continuous layer of hypodermis cells. Next, on the mesal side of the head, a second lobe appears, the lacinia (*lcn.*), or "innere Lade." Both galea and lacinia, then, become toothed on the mesal face, the teeth of the latter being produced each by a single cell; the larger teeth of the former are secreted each by many cells. Eventually (Plate 6, Figure 39) the galea (*ga.*) becomes thickly chitinated except for a central hollow core, but the lacinia (*lcn.*) remains thinly chitinated even in the adult. As in the mandibles, the hypodermis is finally excluded

from the head of the maxilla, but through an opening in the constricted region nerve fibres may be traced to the lacinia.

At this stage (7) the first maxillary palpus (Plate 5, Figure 30, *plp.*), though still present, is no larger than it was in Stage 5 (Figure 22, *plp.*). In the newly hatched insect no trace of this palpus exists, hence it must have been resorbed. In the adult *Orchesella*, on the contrary, the palpus is functional and highly developed; other facts also indicate that *Anurida* is a degraded form.

Von Stummer-Traunfels ('91, p. 226, Taf. I. Figuren 6, 7), following Tullberg ('72, Taf. IV. Figur 17), observed a connection between the maxillary palpi and the so-called paraglossæ of *Collembola*, and makes use of this union (p. 226) as the first of his reasons for recommending an improved designation of the mouth-parts, in the following words: "I. Die grosse Unwahrscheinlichkeit, dass der sogenannte Maxillartaster der *Collembolen* wirklich zur Maxille gehört, indem diese von jenem vollständig getrennt ist und derselbe vielmehr in innigem Verbande mit den Paraglossen steht." Hansen ('93, p. 209) uses this conclusion in proving that the "paraglossæ" of *Collembola* and *Thysanura* are homologous with the first maxillæ of Crustacea. Without discrediting his conclusion, I have already shown (Folsom, '99) upon anatomical data the trivial nature of the union between palpus and "paraglossæ" (superlinguæ). I have now proved upon embryological evidence (Plate 3, Figure 22) that the palpus belongs to the maxilla, and have also shown (p. 114) that the chitinous membrane connecting it with the superlingua is simply incidental, and is only that part of the wall of the maxillary pocket which necessarily intervenes between the first maxilla and superlingua of the same side.

The fundament in *Isotoma* designated first maxilla by Packard ('71, Plate 3, Figure 13) is undoubtedly, from its position in relation to the first pair of legs, second maxilla; therefore what he regards in the same figure as a mandible must be a first maxilla. Ryder ('86) followed Packard in this matter, but Wheeler ('93, p. 57, Figure 6) shows the fundaments in their proper position.

Claypole ('98) correctly identifies the first maxillary fundaments in Figures 43, 46, and 47, but does not mention the palpus.

Uzel ('98) gives a figure of the first maxillary fundaments of *Tomocerus* and remarks (p. 36): "In jenem Stadium, bei welchem die Umröhlung des Keimstreifs vollendet ist, bemerken wir, dass sich die Anlagen des ersten Maxillenpaares (Taf. VI. Figur 87, *mx.*₁) in zwei Höcker getheilt haben, und zwar in einen äusseren länglichen und in einen inneren

stumpf dreieckigen. Der innere Höcker dürfte nach Analogie mit Campodea den lobus internus, der äussere die gemeinschaftliche Anlage des Lobus externus und des Palpus maxillaris vorstellen." I entirely disagree with the author as to the interpretation of the lobes. In Anurida the lobus externus is not developed out of the palpal lobe of the biramous fundament, but the remaining lobe is the common fundament of lobus externus and lobus internus. Therefore Uzel's foot-note on page 36, "An den Maxillarpalpen von *Macrotona* (*Tomocerus*) vulgaris fand ich selbst einen kleinen Vorsprung, der wohl als Lobus externus zu deuten ist," etc., is open to criticism; the minute papilla to which he refers is precisely like several other papillæ distributed upon the palpus (see Folsom, '99, Plate 3, Figure 18, *plp.*), except for a trifling difference in size. It is very doubtful if a difference in this matter exists between Anurida and *Tomocerus*, especially since the process as observed by me agrees with that of insects in general, as far as is known, excepting possibly *Lepisma*, presently to be noticed.

Uzel applied to *Tomocerus* conclusions drawn from Campodea, in which he ('98, pp. 33-34, Taf. VI. Figuren 79, 80) derives the galea from the palpal lobe. His diagrams, unfortunately, do not elucidate the basal relations of the three principal lobes: palpus, galea, and lacinia.

The completed first maxillæ of Campodea (Meinert, '65, Taf. XIV. Figuren 17, 18; Grassi, '86^b, Tav. IV. Figure 2, 13; v. Stummer-Traunfels, '91, Taf. I. Figuren 5, 11) are remarkably like those of *Collembola* (Folsom, '99, Plate 3, Figures 18-21): the cardo is articulated to the superlingual stalk in the same way; the hollow stipes, distinct head, galea, and lacinia are also alike, and resemble less the homologous parts of Pterygote insects. The solid bifid galea and the fringed seven-lobed lacinia of Campodea, as I call them, are by Grassi and v. Stummer-Traunfels regarded collectively as the "innere Lade" or lacinia. The latter author says (p. 223), "Man kann daher bei den drei vorliegenden Formen eine successive Rückbildung des Aussenladens annehmen. Bei *Japyx* noch zweifach gegliedert, ist er bei Campodea schon mehr reducirt und fehlt bei den Collembolen gänzlich." It is curious to observe how authors have followed one another in deriving the galea from the palpal fundament. I have shown in Anurida (anticipating later conclusions) that the galea and lacinia both originate from the "endopodite" of the bifid fundament.

Japyx, of course, agrees substantially with Campodea. The second maxilla, however (Meinert, '65, Taf. XIV. Figuren 8, 9; Grassi, '86^b,

Tav. II. Figure 2, 3, 6, 8; v. Stummer-Traunfels, '91, Taf. I. Figuren 4, 10) has a two-lobed galea and a four-lobed lacinia.

In Japyx, thanks to Meinert's figure ('65, Taf. XIV. Figur 8), the muscles may be clearly homologized with those I ('99, Plate 3, Figures 20, 21) have described for Orchesella. As Meinert did not designate the muscles, I can simply say that they severally correspond with those labelled by me 3. *add.*, 4. *add.*, 10. *add.*, 7. *add.* or 9. *pr't. add.*, and one muscle with both 5. *pr't. add.* and 6. *pr't. add.*, while one of two others probably represents 8. *ret. add.*

In Lepisma, according to Heymons ('97^a, p. 592, Taf. XXX. Figuren 13, 15, 17, 20), the fundament of the first maxilla forms the palpus, at the base of which appears a mesal lobe, which itself divides to form galea and lacinia. This account is, then, at variance with mine on Anurida, that of Uzel on Campodea, and that of Ayers for the Orthopteran genus *Ecanthus*, and is, so far as I know, unsupported by the results of other authors. In fact, Figure 13 of Heymons even suggests that the palpus is a lateral lobe of the primary fundament, as I have found it to be in Anurida. As to the origin of the three first maxillary lobes, Uzel, Heymons, and myself disagree, as I have said. Uzel's account agrees with mine, in so far as he makes the palpus a lateral evagination of the primary, or stipes, fundament; and Heymons, like myself, derives both lacinia and galea from the inner lobe of a biramous appendage.

In its final form, the first maxilla of Lepisma is easily recognized as homologous with that of other Thysanura, but approaches remarkably the same organ in Orthoptera, especially that of the Blattidæ. As in other Apterygota, the stipes (v. Stummer-Traunfels, '91, Taf. II. Figur 11; Muhr, '77, Taf. VII. Figur 45) has a basal opening, cardo, distinct head, galea, and lacinia, and the origin of the muscles (Oudemans, '88, p. 187) "findet man auch hier an Chitinstücken im Kopfe." The palpus in Lepisma, however, is five-jointed, as in Orthoptera. What I call galea and lacinia are also, in this particular case, named "Aussenlade" and "Innenlade" by v. Stummer-Traunfels.

Machilis is nearer than Lepisma to Campodea and Collembola in the structure of the first maxillæ. As may be seen from the figures by Oudemans ('88, Taf. II. Figur 27) and v. Stummer-Traunfels ('91, Taf. II. Figuren 8, 9, 10), the positions of the cardo, stipes, galea, lacinia, and palpus are exactly comparable in the three groups. The palpi in Machilis, to be sure, are seven-jointed, and a palpiger is present, as in Orthoptera. The structure identified by v. Stummer-Traunfels as

"Aussenlade" in *Machilis*, cannot be homologous with the part bearing the same name in other insects, for in *Machilis* it is clearly a part of the palpiger instead of being a constituent of the head of the maxilla. The two adductor muscles described by Oudemans ('88, Taf. I. Figur 19) as extending from the inner wall of the maxilla to a median tentorium, are probably the homologues of 5. and 6. *pr't. add.* of *Orchesella* (Folsom, '99, Plate 3, Figure 20).

In *Ecanthus*, Ayers ('84, p. 241, Plate 18, Figures 20-22; Plate 19, Figure 5) has traced the development of the first and second maxillæ as far as the trilobed condition, his ideas (p. 241) agreeing with mine on *Anurida*: "The primitive appendage is first divided into two lobes, and the inner of these becomes secondarily divided into two." Patten ('84, p. 596) says, "A rather striking variation was found in the first and second maxillæ of *Blatta*, which were formed respectively of two and three lobes." Wheeler ('89, p. 348) adds, regarding the same genus, "The outer of the three lobes of each maxilla becomes the palp, while the inner two become the galea and lacinia of the adult." Heymons ('95^b, p. 19) states that in *Forficula*, "drei selbständige Aeste zu erkennen sind, aus denen Lobus internus (lacinia), Lobus externus (galea) sowie der Palpus hervorgehen." This trilobed stage is exactly comparable with that of *Lepisma*, although Heymons and Ayers differ as to its derivation.

Although Wood-Mason ('79) emphasizes the agreement between *Machilis* and Orthoptera, I may say that *Lepisma* is intermediate between the two in structure, with decidedly orthopteran affinities. Especially is this true of the first maxillæ. The cardo, stipes, galea, lacinia, and palpus of *Lepisma* (Muhr, '77, Taf. VII. Figur 45, or v. Stummer-Traunfels, '91, Taf. II. Figur 11) not only agree in position with those of *Blatta* (Muhr, '77, Taf. II. Figur 12, or Packard, '83^a, Plate XXVIII. Figure 12, *Periplaneta*), but exhibit a surprising agreement in form, as well as the number of palpal segments; in both groups, also, a palpifer is differentiated. Through *Lepisma*, therefore, the first maxillæ of *Collembola* may be homologized with those of Orthoptera, and hence all other Pterygote orders. I have traced the homologies, part for part, between *Lepisma* and all the families of Orthoptera, as well as the genera *Ephemera*, *Myrmeleon*, and *Corydalus*, in which latter genera the nymphal first maxillæ are but little specialized in form. Heymons ('96, p. 19) states that in the Libellulid genus *Epithecä*, "Erst später gliedert sich von der Aussenseite der Maxille eine kleine rundliche Erhebung ab, welche die Anlage des Tasters darstellt (Figure

19, *palp. mx.*¹), während das in der directen Fortsetzung des ursprünglichen Maxillen-Zapfens liegende Endstück zur Lade (*lobus*) wird." This agrees with Anurida, Campodea, and Ecanthus, but disagrees with the account given by Heymons himself for Lepisma.

Turning to the Myriopods, Scolopendrella, while undoubtedly more closely allied to the Diplopods, nevertheless shows in many ways interesting correspondences with Campodea, as other writers have already stated. The lateral parts of the plate termed the "gnathochilarium" resemble in several respects the first maxillæ of Campodea. According to Latzel ('84, Taf. I. Figuren 6, 7) and Grassi ('86^a, Tav. II. Figure 5, 10), there is an elongated hollow stipes bearing an outer (galeal) and also an inner (lacinial) terminal lobe, both of which agree in detail with the comparable structures of Campodea and Japyx; for in Campodea, a one-jointed palpus is present, and in Campodea, Japyx, and Collembola, a "chitinous rod" extends backward from the lacinia. The few muscles shown by Latzel ('84, Taf. I. Figur 7) are to be compared with 5. and 6. *pr't. add.*, and 8. *ret. add.* of Orchesella (Folsom, '99, Plate 3, Figures 20, 21). Grassi ('86^a, p. 16) states that muscles from within the organ pass to an endoskeleton, which, as one may see from his Figure 25, is essentially like the "lingual stalks" that I have found in Orchesella and Anurida, and still more nearly like the same structure of Campodea and Japyx. All these similarities confirm the view, based primarily upon other anatomical data, that Scolopendrella most clearly represents the hypothetical ancestor of insects.

Among Diplopods the passage from the more generalized genera, as Lysioptalum or Craspedosoma, to Scolopendrella is clear. In the first genus, especially, are seen a cardo (not described as yet for Scolopendrella), stipes, galea, and lacinia, all simple in structure, but no palpus. I should state, however, that it remains to confirm these homologies by embryology.

In Campodea the second pair of jaws is usually homologized with the first maxillæ of Insects; but, except in position, there is little resemblance between the two organs.

The first maxillæ of insects are usually homologized with the first maxillæ of Crustacea, but if, as I maintain, the "superlinguæ" are equivalent to the latter organs, it follows that the hexapod first maxillæ correspond to the Crustacean second maxillæ.

The primitive biramous character of Crustacean mouth-parts is well known, and Hansen ('93, p. 198) has, in connection with this subject,

formulated a significant law — “dass man drei Glieder im Stamm von allen gespalteten Gliedmassen bei den Crustaceen als ein primäres Verhältniss annehmen muss, und diese Zahl hat sich, wenigstens in den angeführten Fällen, deutlich erhalten.” In fact, Hansen himself (p. 206) has homologized the first maxillæ of *Machilis* with the second maxillæ of Crustacea, on account of the three axial segments and the position of the palpus, saying: “Der Bau der Maxillen . . . stimmt also genau mit den Maxillen der Eumalacostraken.”

The axial segments of the Crustacean appendage are on this view successively equivalent to cardo, stipes, and palpifer of Hexapoda.

It must be admitted that these anatomical agreements, if appealed to alone, may logically be used to support other views than my own, since all the Crustacean appendages are constructed upon the same plan; but the equivalence of the neuromeres in Hexapoda and Crustacea is a matter of the greatest significance. Viallanes has proved that the first three neuromeres in the two groups agree in great detail, and I find that his conclusions apply equally well to the succeeding neuromeres. It is very significant that in most cases the appendages of equivalent somites have the same function in the two groups, and that all the paired nerves of the head in *Collembola* agree exactly in position with those of decapod Crustacea.

Summarizing: The first maxillæ of Apterygota develop in all essential respects like those of Orthoptera, with which they may be homologized in detail. In Anurida a palpus appears, but is resorbed before hatching, indicating the descent of Anurida from a form in which the first maxillary palpi were functional. The first maxillæ of Campodea are clearly to be homologized with those of Scolopendrella, and less clearly with the lateral portions of the Diplopod gnathochilarium. The first maxillæ of Hexapoda pass through a biramous stage, such as obtains among Crustacea, are comparable with Crustacean second maxillæ in some detail, and are homologous with those of Malacostraca.

Labium.

The fundamentals of the labium, or “second maxillæ,” appear next after those of the first maxillæ, and at Stage 1 (Plate 1, Figure 1; Plate 2, Figure 8, *mx.*²) are a pair of simple conical elevations rising perpendicularly from the germ band and slightly longer than the fundamentals of the mandibles and first maxillæ. In the following stage (2) they are longer and more cylindrical (Figure 2); in Stage 3 (Figure 3)

they are somewhat larger, and ventral or lateral surface views of the germ band (Plate 2, Figures 9, 10; Plate 3, Figure 11) disclose a distinct lateral lobe, the palpus (*plp.*), which is larger than that of the first maxilla. A second maxilla, as dissected out at this stage, is shown in Figure 18 (Plate 3). Transections of the germ band (Plate 3, Figure 14) show the palpus to be an outfolding of the antero-lateral face of the primary maxillary evagination, just as in the case of the first maxilla.

At this stage (Plate 2, Figures 9, 10) there appears near the mandibles a lateral evagination (*pli. or.*) of the germ band, destined to form the side of the face; this fold grows backward until it involves the base of the second maxilla of the same side, and the internal cavities of the two folds become one. In Stage 4 (Figure 4; Plate 3, Figure 19) it has already involved the base of the second maxilla; the apex of the maxilla, however, is still free from the fold, and the palpus (Plate 3, Figure 12, *plp.*) is as large as that of the first maxilla.

At Stage 5 the second maxillæ (Figure 5; Plate 3, Figure 20, *mx.*²) are long, oval in cross-section, and project at right angles to the germ band; the antero-lateral region of the base is confluent with the mouth-fold (Figure 21). At this period all trace of the second maxillary palpus becomes lost; it has not become involved in the mouth-fold, which is still restricted to the base of the maxilla, but has been rapidly resorbed and appears at last as indicated in Figure 20. In the next stage (6) the second maxillæ (Figure 6) converge toward the median plane like the other pairs of oral organs, and similarly swing forward.

At Stage 7 (Plate 2, Figure 7) the second maxillæ and mouth-folds are quite confluent (Plate 5, Figures 30, 34), but the anterior part of each maxilla is still distinguishable as a swollen lobe, or less flattened region (Plate 4, Figure 24, *lab.*). The bases of the second maxillæ, although widely separated in Stage 5 (Plate 3, Figure 21, *mx.*²), subsequently spread toward the median plane, become thinner, and gradually form a single plate; the median sinus between them shortens until the condition shown in Plate 5, Figure 29 (*lab.*) is attained. The union of the second maxillæ with each other is not a simple contact and fusion resulting in a median suture; but a confluence of the cavities of the two maxillæ occurs and progresses forward (*i. e.*, distally), ceasing, however, before obliterating the median sinus, which remains in the adult (Plate 7, Figures 43, 45, *sut. m.* and *sul.*). Although the finished labium bears a median ventral groove, the groove does not indicate the fusion of the fundaments; at Stage 7, when the labial plate is complete, no trace exists of the groove, which is formed in a later stage. A comparison of

my figures (Plate 3, Figure 20; Plate 5, Figure 29) will show that practically the entire ventral surface of the head is labial in origin, because the original bases of the second maxillæ extended quite to the first pair of legs; an inconsiderable, if any, portion of the germ band intervening (Figure 21) between them.

At Stage 8 the mouth is nearly closed (Plate 5, Figure 34) by the overgrowth of the combined second maxillæ and mouth-folds.

In the adult (Plate 7, Figure 43) the apical lobes, although in contact mesally and stoutly chitinized, are readily separable and may be depressed and elevated by muscles homologous with those of *Orchesella*, the hinge lines being shown at *sut.* Shortly before hatching, hypodermis cells evaginate singly to form the external setæ of the head.

In the development of the labium, as I have traced it, neither galea nor lacinia becomes differentiated; but the terminal lobe is equivalent to the head of the first maxilla, and therefore represents the common fundament of galea and lacinia, the second maxilla not passing the biramous stage. All of the labium behind the terminal lobe represents not only the stipes and cardo of the first maxilla, but also the mentum, submentum, and gula of the Orthopteran labium, — an important conclusion.

In *Orchesella* (Folsom, '99, Plate 3, Figure 24) mentum, submentum, and gula appear to be indicated, but the development in *Anurida* throws no light upon the structures which I suggested might be modified palpi.

Packard ('71, p. 17) in describing *Isotoma* says, "I was unable at this or any other period to discover any traces of the second maxillæ. Though existing in a very rudimentary state in the adult, I could not detect them after repeated attempts, but do not doubt but that a more skilled observer would have made them out. Indeed, it is a most difficult thing to discover their rudiments in the adult; I failed, at the time these observations were made, to detect them, though since then I have succeeded in making out their structure and relation to the surrounding parts of the mouth." As a matter of fact, he (Plate 3, Figure 13) has evidently figured the second maxillæ, which I know to be present in the genus, and in the passage quoted he doubtless referred to the superlinguæ ("paraglossæ"), which Lubbock also ('73, p. 66) termed "second maxillæ." Ryder ('86, Plate XV. Figures 7, 9, 10), too, repeated the mistake in *Anurida*.

Claypole ('98, Plate XXIII. Figures 40-44, 46, 47) represents the fundaments as simple papillæ without distinguishing the palpi, which are, however, obscurely indicated in Figures 43 and 47.

Uzel ('98, Taf. VI. Figur 87) shows the papillæ of the second maxillæ in *Tomocerus*. Concerning the development of the second maxillæ in *Campodea*, he ('98, p. 33) says, "Auch an den Anlagen der zweiten Maxillen (Taf. IV. Figur 38 und Taf. VI. Figur 79, mx_2) lässt sich ein kleinerer lateraler und ein grösserer medialer Theil unterscheiden, die indess nicht scharf von einander gesondert sind." . . . (p. 34) "An den Anlagen der zweiten Maxillen tritt auf der Mitte des Hinterrandes ein Vorsprung auf (Fig. 80, le_2), aus welchem sich, wie wir voraussenden wollen, der Lobus externus entwickelt, wogegen der früher besprochene innere Theil den Lobus internus (li_2) und der äussere den Palpus labialis (pmx_2) aus sich entstehen lässt. Zugleich bemerkt man an den beiden Maxillenpaaren eine gewisse Rotation. Die äusseren Enden derselben bewegen sich nämlich nach vorn (Fig. 80), so dass die beiden Anlagen eine schräge Stellung erhalten. Bald jedoch, und zwar in dem Stadium, wo die vollkommene Umrollung des Keimstreifs zustande gekommen ist (Fig. 41), kehren sie in die ursprüngliche Lage zurück (das erste Maxillenpaare nicht ganz), und es erfolgt nun eine Rotation des zweiten Maxillenpaares allein im entgegengesetzten Sinne; die äusseren Enden desselben bewegen sich nämlich jetzt nach hinten und drehen die ganze Anlage in eine entsprechende schräge Lage, welche aus Fig. 81 ersichtlich ist.

"Im nächsten Stadium (Fig. 82) . . . die Anlagen des zweiten Maxillenpaares haben eine dreilappige Gestalt angenommen. Die drei Lappen lassen sich leicht deuten, wenn man die vorhergehenden Stadien vergleicht. Der vorderste (li_2) entspricht dem Lobus internus, der mittlere (le_2) dem Lobus externus, und der hintere, breit gerundete (pmx_2) stellt den Palpus labialis vor. Auch bemerken wir, dass sich nach der erwähnten Rotation die beiden Anlagen des zweiten Maxillenpaares einander stark in der Medianlinie genähert haben (Fig. 82) und auch etwas nach vorn gerückt sind." "In den nächsten Stadien (Fig. 83 und 84), bei welchem der Keimstreif schon etwas spiralig gerollt erscheint (Fig. 42), rücken die Anlagen des zweiten Maxillenpaares noch näher aneinander, und zwar ganz besonders die Lobi interni (li_2)." In the postembryonic stage (p. 47): "Die beiden Anlagen des zweiten Maxillenpaares rücken in der Mittellinie noch näher als früher zusammen, so dass nicht nur die Lobi interni ($limx_2$), welche sehr gross geworden sind, sondern auch die Lobi externi ($lemx_2$) dicht neben einander zu liegen kommen. Eine Verwachsung der beiden Hälften des zweiten Maxillenpaares findet jedoch auch beim erwachsenen Thiere nicht statt."

It is not clear, then, whether the galea develops from the outer or the inner lobe of a biramous appendage, although Uzel's account is, at least, not inconsistent with his description of the first maxillæ, which I have already criticised. Although Uzel does not state as much, his figures indicate the palpus to be an appendage of the primary fundament, as it is in Anurida. In this genus, however, no third branch appears, as I have said; but, from analogy with the first maxilla, the inner of the two branches represents undifferentiated galea and lacinia.

The rotation in a frontal plane of the second maxillary fundament of Campodea — which does not occur in Anurida — enables me to homologize the finished labium of Campodea with the apparently different labium of all other insects. If Uzel's figures are compared with Figure 12 of v. Stummer-Traunfels ('91), it is easy to see that the embryonic structures by Uzel designated *limx*₂ (lacinia), *lemx*₂ (galea) and *pmx*₂ (palpus) are with hardly a doubt respectively represented in the adult by the parts which v. Stummer-Traunfels termed *up*. ("untere Mundplatte"), *pl*. ("tasterförmige Papille") and *pp*. ("Tastwarze"). These homologies, however, could never have been settled upon merely anatomical grounds.

What Grassi ('86^b, Tav. IV. Figura 3), then, considered to be the under lip (*la. in.*) of Campodea is but the anterior part of the true labium; the "labial palpi" (*pa. li.*) are really galeæ borne upon a region representing the mentum, and the "labial papillæ" (*pa. la.*) are but modified palpi. As in Collembola, the labium is anteriorly and deeply cleft.

Japyx is so close to Campodea that the same conclusions may doubtless be applied to both genera. In Japyx the labium, as in Collembola, is split and bears a median sulcus (Grassi, '86^b, Tav. III. Figura 21) much like that of Orchesella (Folsom, '99, Plate 4, Figure 29). Examining Figure 1 of v. Stummer-Traunfels ('91, Taf. II.), the lacinia and galea are clearly represented, as in Campodea; the true palpus, however, is but obscurely differentiated in the region behind the so-called palpus (*pl.*) and nearer the median plane. The eversible papillæ of the anterior part of the labium, as described by Meinert ('67, p. 369) and Grassi ('86^b, p. 31), are probably homologous with the papillæ of Orchesella which I designated *plp.* ('99, Plate 3, Figure 24).

For Lepisma, Heymons (97^a, p. 590, Figur 11) gives, first, a pair of simple second maxillary fundaments and later (Taf. XXX., Figur 20) a long palpus with a small, basal, inner lobe, and states (p. 592) "Die Lobi oder späteren Lidentheile der Maxillen sind in diesen Stadien erst

als sehr kleine unscheinbare Vorsprünge erkennbar, welche medialwärts an der Basis der Taster hervorwuchern." This is contrary to the conditions in *Anurida*, where the palpus is certainly itself an outgrowth from the simple, primary papilla (Figure 13). *Lepisma* agrees with *Anurida*, however, in that the galea and lacinia are derived from the inner lobe of a biramous fundament (Heymons, '97^a, Taf. XXX. Figur 17), and disagrees with *Campodea* if, in the latter genus, as Uzel implies, the galea buds from the palpus. The finished labium of *Lepisma*, as I shall show, is remarkably like that of *Orthoptera*.

The labium of *Machilis*, as described by Oudemans ('88, pp. 185-186, Taf. II. Figuren 28, 29), resembles that of *Campodea* and *Collembola* in being deeply cleft, and having the salivary ducts opening in similar positions, but it more nearly approaches the *Orthopteran* type in the position and structure of the terminal lobes, the mentum, and the three-jointed palpi. Each terminal lobe is subdivided into four lobes, which in all probability collectively represent galea and lacinia.

Ayers ('84, p. 241, Plate 18, Figures 20-22; Plate 19, Figure 5), as already quoted (p. 124), has traced the development of the second maxillæ of *Æcanthus* as far as the trilobed stage, stating the lobation to be more prominent in the second than in the first maxillary appendage. The fact that the second maxillæ of *Anurida* develop upon the *Orthopteran* type is important. In *Lepisma*, the trilobed fundaments agree with those of *Orthoptera* even as to the greater length of the palpus.

In the finished labium of *Æcanthus* (Packard, '83ⁱ, Plate XXVII. Figure 9) the derivatives of each trilobed fundament are easily identified as three-jointed palpus, galea, lacinia, palpifer, and mentum, — the last two structures having doubtless arisen from the common stalk, or stipes. Although the labium is constructed upon the same plan in all *Orthoptera*, we may best select *Blatta* for comparison with *Lepisma*. The agreement between *Blatta* (Muhr, '77, Taf. II. Figur 11; Packard, '83ⁱ, Plate XXVII. Figure 14) and *Lepisma* (Muhr, '77, Taf. VIII. Figur 46; v. Stummer-Traunfels, '91, Taf. II. Figur 17) is surprising. Galeæ and laciniae clearly correspond in the two, as do the mentum, palpifers, and palpi, the last, however, having three segments in *Blatta* and four in *Lepisma*. Muhr, in fact, included *Lepisma* among *Orthoptera*, as have some other authors.

It is now agreed that the first and second maxillæ of *Orthoptera* are homodynamic, and, more inferentially, that the same is true of other insects. The exact agreement first recognized, according to Packard ('98, p. 69), by Miall and Denny ('86), was detected long before, at least, by

Muhr ('77, p. 9) and by Schaum ('61, p. 84). In Anurida the whole gular region, excepting the terminal lobes and palpi, represents the undifferentiated gula, submentum, mentum, and palpifers; therefore the gula in Orthoptera may be regarded as the united cardines, and the submentum, mentum, and palpifers, as stipes derivatives. It will be seen that my view differs from those accepted and defended by Packard ('98, p. 69) and others; but it is supported by embryological evidence, while the other views are not. It may safely be predicted that the apparently unpaired gula of Orthoptera will be shown to originate from paired fundaments, as I have found it to do in Anurida.

If these homologies between Collembola, Thysanura, and Orthoptera are accepted, their extension from the last group to other Pterygote orders is not difficult, even though the desirable embryological verifications are still wanting.

There is an unfortunate confusion of terminology regarding the mouth-parts of insects. The homologies are much obscured, but less by the use of different terms for homologous parts, than by the use of the same name for parts which are not homologous. "Paraglossæ" and "ligula" are cases in point. To most entomologists "paraglossæ" mean indifferently the labial lobes homodynamic with the galeæ and the laciniae of the first maxillæ, or else mean the galeal lobes alone, while "ligula" or "glossa" signifies the lacinial lobes, often more or less fused into a median organ; in fact, "ligula" is often used synonymously with "labium" in reference to many Coleoptera (Le Conte and Horn, '83, p. xviii). "Ligula," however, is often made a synonym of "lingua" (Packard, '98, p. 68), and the latter term, of "hypopharynx." In my opinion, the term "lingua" should be restricted to the median, unpaired constituent of the hypopharynx; for the "hypopharynx" of certain insects often bears two dorso-lateral lobes which in more generalized insects are not only free from the lingua, but quite distinct from it in origin (as proved by myself in Anurida and by Uzel in Campodea), and these dorso-lateral appendages are most frequently called "paraglossæ," upon assumptions which are not sustained by embryology, as I shall presently show.

As the terms "paraglossæ" and "ligula," or "glossa," are irremovably fixed, as applied to labial structures, they should not be used for anything else. It is both unnecessary and impossible to displace the term "hypopharynx," but it is necessary to recognize the overlooked fact that the "hypopharynx" is frequently a compound organ, to the ventral and median component of which the term "lingua" may well

be restricted ; while, for the dorso-lateral appendages, rejecting "paraglossæ," I propose the more appropriate name "superlinguæ."

The "gnathochilarium" of Symphyla and Diplopoda may also prove to be in part homologous with the hexapod labium. Having already discussed the resemblances between the lateral portions of the gnathochilarium and the first maxillæ, I may compare the median components with the labium. They were, in fact, designated "under lip" in *Scolopendrella* by Grassi ('86^a, Tav. II. Figura 5). As in Apterygota, there is a median portion and two stipal plates, each of which bears a papillate head, separated by a transverse suture. These are the only points of agreement. On the contrary, the gnathochilarium is usually homologized with the first maxillæ of insects (Packard, '83^b, p. 199; Korschelt u. Heider, '90-93, p. 906) — apparently on account of Metschnikoff's ('74) researches. I can only suggest that the under lip of Diplopods is anatomically of too compound a nature to be homologized with the first maxillæ only, and that we are not warranted in deriving the entire lip from only two primary fundamentals simply because Metschnikoff did not allude to more than two. In fact, Heymons ('97, p. 7, Figur 2) has discovered a "post-maxillary" segment, without appendages, in the embryo of *Glomeris* ; but he regards it as equivalent to the labial segment of insects. In other Diplopoda, for example *Lysiopetalum* (Latzel, '84, Taf. IX. Figur 104) and *Craspedosoma* (Latzel, '84, Taf. VI. Figur 72), the structure of the under lip is remarkably like that in *Scolopendrella*.

In Chilopoda there are two fleshy, jointed appendages ("first maxillipedes," "zweites Unterkieferpaar"), which are conceivably equivalent, in position only, to the second maxillæ of Hexapoda, and are generally homologized with the first pair of legs of Diplopoda. If the second maxillæ of insects are represented among Diplopoda in the manner I have suggested, then the second pair of Chilopod "maxillipedes" ("Kieferfusspaar") corresponds with the first pair of feet of both Diplopoda and Hexapoda, — a simple conception.

The labium of Hexapods is homologous with the first pair of maxillipeds of Crustacea, according to the homologies which I have already proposed for all the more anterior paired appendages. It is, then, erroneous to homologize with each other the second maxillæ in these two classes; but the error is so firmly established that I have in this paper frequently employed the term "second maxillæ" for the labium of insects, in order to avoid confusion.

The evidence for my view of the homologies of the labium is of the

same character as that already used for the "first maxillæ." The labial fundamentals are appendages of the seventh somite in both Hexapods and Crustacea and are supplied by equivalent ganglia and nerves. In both groups each fundament is at first simple and secondarily develops a palpus, or exopodite. Moreover, the axis of the appendage is three-segmented, the segments in Crustacea corresponding to gula, mentum, and palpifers of generalized Hexapoda, the submentum being a secondary development.

Hansen ('93, p. 206) differs slightly: "Das Submentum [Machilis] ist mit dem, bei den Gammarinen zusammengeschmolzenen ersten Gliede homolog, das Mentum mit dem bei den Hyperinen auch zusammengeschmolzenen zweiten Gliede; auf der Spitze des Mentums findet man ein Glied, das auf jeder Seite in vier Laden ausgeht, die, wie sich ziemlich deutlich zeigt, zwei Laden angehören, die jede für sich gespalten ist, und diese halte ich (unter Anderem wegen eines Vergleiches mit Orthoptera und Amphipoda, kann aber keinen zwingenden Beweis von den Skelettheilen führen) respectiv für eine Lade vom zweiten Gliede (die innerste gespaltene Lade) und für das dritte Glied des Labiums mit seiner gespaltenen Lade; der Palpus geht von der Aussenseite des dritten Gliedes aus."

Hansen should have taken into consideration the gula, and the fact that the submentum is probably not a primitive sclerite.

The homologies between Hexapoda and Crustacea that I have defended are none the less valid if the total number of somites differs in the two classes, and they are sustained if the number is the same. In decapod Crustacea there are twenty-one somites, including the ocular segment. In generalized insects the number of abdominal segments varies. In the embryo of *Lepisma*, which shows marked affinities with Crustacea and Orthoptera, Heymons ('97^a) finds eleven abdominal somites. Add to these the thoracic segments and the seven which I have found in the Apterygota head; and the total, twenty-one, is the same as for decapod Crustacea. In embryos of many families of Orthoptera and Odonata just eleven abdominal segments are present. On the other hand, Heymons ('95^b) has found twelve in certain genera of the same orders, and in *Collembola* the number varies greatly. In view of this variability within the limits of the same order, then, it is well not to emphasize the agreement between generalized insects and decapod Crustacea in the total number of somites.

My conclusion regarding the labium, then, is that its development in Apterygota conforms to the Orthopteran type. In Anurida a labial pal-

pus is formed and resorbed, — an indication of degeneracy. The entire gular region of Apterygota is labial in origin; but fewer sclerites are differentiated than in Pterygote insects. The labium of insects is homodynamous with the “first maxillæ” and homologous in detail with the first maxillipeds of decapod Crustacea. The labium of Campodea is equivalent to the “second maxillæ” of Symphyla, and is represented in the Diplopod gnathochilarium.

Skull.

The principal mouth-parts of Collembola, unlike those of all other insects, except certain Thysanura, are internal; the way in which they become so will now be described.

The beginning of the process is seen at Stage 3 (Plate 1, Figure 3), when the ventral surface of the germ band is almost flat. In lateral aspect (Plate 2, Figures 9, 10) the edge of the germ band is produced downward as a small crescentic lobe (*pli. or.*) outside the fundaments of the mouth-parts. This lobe usually originates on the mandibular segment, as represented in Figure 9, but may arise more anteriorly, as in Figure 10. These figures represent, respectively, the left and right sides of the same individual. Rarely, the lobe begins behind the mandible. A transection of the germ band near the middle of the lobe (Plate 3, Figure 16) proves the lobe (*pli. or.*) to be an evagination of the ectoderm enclosing mesoderm. In ventral aspect at this stage (Figure 11) the mouth-fold is clearly distinguishable at its widest part, or place of origin, but gradually disappears anteriorly and posteriorly on account of its confluence with the rest of the germ band.

At Stage 4 (Plate 1, Figure 4) and a little later, while involution of the germ band is occurring, the mouth-fold is considerably larger (Figures 12, 19, *pli. or.*) and forms a crescentic flap, now extending from the second maxilla almost to the labrum. In the next stage (Plate 1, Figure 5) the fold is conspicuous; in lateral aspect (Plate 3, Figure 20) its ventral margin is well rounded and conforms posteriorly to the contiguous anterior surface of the front leg; the mandibular and maxillary fundaments still project slightly below the fold. In ventral aspect (Plate 3, Figure 21) of the same individual, the fold is seen to be of nearly uniform width except anteriorly and posteriorly, where it is expanded against the labrum and second maxillæ respectively. Transections of the germ band (Plate 4, Figure 23), when compared with similar sections at Stage 3 (Plate 3, Figure 16), show the folds to have exceeded

the mandibles in rate of downward growth, and the lateral surface of the mandible to be concave, in conformity with the swollen distal region of the mouth-fold.

In Stages 6 and 7 (Plate 1, Figure 6; Plate 2, Figure 7) the folds involve the labrum and second maxillæ (Plate 4, Figure 24; Plate 5, Figure 30, *pli. or.*), covering the mandibles and first maxillæ laterally, and forming the genæ, or sides of the face. As seen in Stage 7 (Plate 5, Figure 30), each oral fold connects one side of the clypeo-labral fold with the labial evagination of the same side. There are no sutures, however, to indicate the union of the genæ dorsally with the clypeus and ventrally with the second maxilla, for the oral evagination, in its backward and forward extension, has at length involved the labial and clypeal folds, respectively, in such a way that all three folds become one and enclose a single common cavity. The anterior margin of the mouth-fold is still distinguishable, however, as late as Stages 7 and 8 (Plate 4, Figure 24, *pli. or.*); the mesal surfaces of the labial fundaments have not united anteriorly (Plate 5, Figure 29); the labrum is free from the fold (Figure 30) and remains so. The mouth is definitely bounded, but still open (Figures 30, 34); its closure occurs, however, before the egg hatches. The folds — clypeo-labral, oral, and labial — have been converging concomitantly with their elongation, and continue to elongate and converge until they meet to form a buccal cone, which completely encloses the inner mouth-parts. After hatching, there is, for reasons just given, no demarcation of the mouth-fold; it can simply be said that the region designated as *pli. or.* in Figure 40 (Plate 6) is the anterior part of that fold. Also in *Orchesella* the corresponding region, under which project the palpi (Folsom, '99, Plate 2, Figure 9), doubtless originates as in *Anurida*, but the clypeus is not confluent with the folds.

Strictly speaking, then, the mandibles and maxillæ are *not* "retracted," as is usually stated; but they are overgrown by the genæ.

Hansen ('93, p. 208) wrote concerning Campodea, Japyx, and Collembola, "die Mandibeln und Maxillen, mit Ausnahme der Spitzen, 'im Kopfe liegen.' Dieses ist dadurch entstanden, dass sich die Haut hinter ihrer Einlenkung wie eine Duplicatur, welche Gewebe enthält, vorwärts und um sie herum gefaltet hat, und die Ränder dieser Duplicatur sind auf der Unterseite des Kopfes mit dem Seitenrändern des Labiums festgewachsen, so dass dieses fast seiner ganzen Länge nach mit der Seitenwand des Kopfes verbunden ist." These facts he ascertained by laborious dissections of the finished parts.

Packard ('71, p. 21) simply mentions that "the cephalic plates, which

fold back upon the head, forming the main expansion of the insectean head is [are] apparently the tergum of the antennary segment," — a statement unsubstantiated by later and more extensive studies.

The only account of the formation of the mouth-folds of *Collembola* is by Miss Claypole, who also studied *Anurida maritima*, giving her results briefly in 1896 and finally in 1898. The following extracts from her valuable paper ('98, pp. 264–266) summarize her observations and conclusions: "On each side of these [three pairs of mouth-parts, as in my Stage 3] has appeared a ridge that passes backward along the embryo, the two folds enclosing the mandibles and maxillæ. These folds start from just the region where the small intercalary appendages were seen earlier, but which have now disappeared. Figures 43, 46, and 47 show the process by which this change takes place, and leave no doubt that the folds, as they finally appear, are a development from the intercalary appendages. . . . The labrum in front and these lateral folds make together a three-sided box in which the mouth-parts, two mandibles, and four maxillæ are sheltered. . . . The second pair of maxillæ has been modified to form the back of this pouch." The author (pp. 265–266), after homologizing the neuromeres of *Orthoptera* and *Crustacea*, draws the important conclusion that the mouth-folds of *Anurida* "including without doubt its allied forms," are "clearly homologous with the second antennæ" of *Crustacea*.

I quite disagree with this author as to the origin, and consequently the homology, of the mouth-folds. A priori arguments are here superfluous, as the question is one of fact. As I have shown, the folds begin on, or very near, the mandibular segment, but always outside the paired fundaments of the mouth-parts, and never at the premandibular appendages. The folds eventually and necessarily involve the intercalary region on progressing towards the labrum, although previously their early indicated continuity with the second maxillæ (Plate 2, Figure 10) is established. Conceptions as to the development of the fold are of course but inferences from facts observed in certain stages. The most apparent inference from the figures cited by Miss Claypole as leaving no doubt about the accuracy of her conclusion is certainly the one she has drawn; but from the same figures and from her preparations — which Miss Claypole has most kindly lent me — may also be drawn the less apparent, though I believe correct, inference that the folds begin between the intercalary and second maxillary regions and grow towards both of them. I have found stages intermediate between those shown by Miss Claypole in Figures 46 and 47, which convince me that this is the

case. Consequently the mouth-folds cannot represent the Crustacean second antennæ. My own views as to the homology of the mouth-folds, already implied by my use of the term "genæ," will presently be supported.

Hansen's recognition of the similarity between Campodea, Japyx, and Collembola is sustained by embryology. In Campodea, Uzel ('98, p. 33) describes and figures a "Chitinstrang . . ., welcher sich von der Vorder- randmitte der zweiten Maxille um die Aussenseite des ersten Maxille und der Mandibel herum zu den auf den Intercalarsegmente gelegenen Höckern zieht." His Figures 38 and 79 show the Chitinstrang at a rather advanced stage of development, corresponding with the condition in my Figure 17; unfortunately he gives neither its origin nor its earlier development. The later development, as evidenced diagrammatically by his Figures 80-84, agrees with that of Anurida in the gradual approximation of the lateral ridges, and especially in the completion of the buccal boundary by the same method of confluence. Uzel does not attempt to explain the homology of the Chitinstrang.

In *Lepisma* and *Machilis* the mouth-parts are ectognathous, as in Orthoptera. In *Lepisma* there is no trace of a lateral mouth-fold, but in *Machilis* I have found a distinct, flat, lateral lobe sheltering the base of each mandible, and the lobe is probably homologous with the Collembolan mouth-fold.

In Pterygota the genæ, often not demarcated as distinct sclerites, represent the lateral regions of the germ band — as they do in Campodea and Collembola. In these Apterygota the same areas have simply increased as folds, but the folds are none the less homologous with the pleural regions of other insects, and in Collembola are reasonably to be regarded as the pleural portions of the premandibular, mandibular, and both maxillary segments. In many Pterygote insects, especially in Orthoptera, the genæ overlap the bases of the jaws; for example, in *Caloptenus*, in which the gena is produced as a small but distinct flat fold over the base of the mandible.

Little is known about the development of the sides of the head in Myriopoda, but in *Peripatus* it is interesting to find distinct lateral mouth-folds (Sedgwick, '88, Plate II., Figure 36) quite analogous, to say the least, with those of Collembola.

Concerning the completion of the skull, little remains to be said. At Stage 7 a constriction encircling the blastoderm separates the head from the thorax. The head is typically a hollow cylinder, or cone, and so is the body. The body cylinder consists of a definite number of successive

rings, in each of which, in the more specialized insects, tergum, pleura, and sternum are present.

In the head region of the Collembola, however, segmentation occurs only on the ventral side of the germ band. The entire gular region is labial in origin, and there is reason for regarding the clypeus as the tergite of the ocular segment. The mouth-folds are undoubtedly expanded pleura. Aside from these, however, it is idle to speculate about the location of other sclerites which are differentiated in more specialized insects. Here, in the absence of such differentiation, it may be said that the head-cylinder represents seven ideal rings, which dorsally and laterally are in no way demarcated from each other. Admitting that the procephalic lobes do extend backward and encroach upon other segments, the lobes may not be regarded as the tergites or pleurites of those segments, for they are simply thickened blastoderm, and increase in area in proportion as the blastoderm thickens; but the convenience of applying a single term, "procephalic lobe," to either of these thickenings should not blind us to the fact that the lobe eventually represents the blastoderm of more than one segment.

In the finished head (Plate 5, Figure 33) are certain elevated dorsal areas which, however, are not sclerites bounded by sutures, and are not clearly to be homologized with sclerites of other hexapod orders. The elevations referred to are directly correlated with underlying glands and muscles.

The sides of the face in Apterygota, then, are homologous with the genæ of Pterygota. In all insects the skull represents seven somites, but the cephalic sclerites of Pterygota, excepting labrum, clypeus, and labial sclerites, are not differentiated in the Apterygota.

Tentorium.

The tentorium of Anurida is essentially like that of Orchesella (Folsom, '99), consisting of a chitinous plate parallel with the frontal plane (Plate 8, Figure 51, *tnt.*), from which diverge two pairs of chitinous arms (Plate 6, Figure 35) extending to the skull: a dorsal pair (*br. d.*) and a posterior pair (*br. p.*) embracing respectively the supra- and infra-œsophageal ganglion. A third, or anterior, pair was found in Orchesella, but not in Anurida.

Regarding the development of the tentorium in insects, most diverse opinions are held. After considerable study, I have come to the con-

clusion that the tentorium of Anurida is derived from proliferated ectodermal cells which are in no way, except in position, distinguishable from young ganglion cells.

In Anurida, as in Orthoptera (Wheeler, '93, Heymons, '95^b) and Lepisma (Heymons, '97^a), the ventral cords consist of dorso-ventral rows of cells, which arise by proliferation from the outer ectoderm. Although it has seldom been supposed that these cells became other than ganglionic in function, it may be assumed, in view of their origin, that all of them are potentially chitin-forming cells, and it seems probable that some of them actually do form the chitinous tentorium.

An oblique section of Stage 8, cut at a fortunate angle for studying the relation of tentorium to cells, gave the appearance represented in Figure 35. Contiguous to practically all parts of the tentorium, in this section, are cells the nuclei of which do not differ in appearance from nuclei of undoubted ganglion cells. On all sides of the tentorium such cells abound and closely embrace it; an especially large mass of these cells occurs immediately under the frontal plate, in which, moreover, several cells always become enclosed and appear to be functional in the adult. I found no evidence which could be interpreted as indicating any other way of formation.

Von Stummer-Traunfels ('91) appears to have overlooked the tentorium of Apterygota, for he mentions the "Stützapparate" only, by which he evidently means the structures I call "lingual stalks."

As regards the Thysanura, Meinert ('65, Tab. XIV. Figur 5, *b*) mentions in Japyx and Campodea a median chitinous plate, from which the mandibular adductors take their origin, which is undoubtedly the tentorium. Grassi (86^b) also alludes to it in Japyx.

In Machilis the lingual stalks, important in Collembola, become rudimentary; and most of the mandibular and maxillary muscles become attached to the tentorium; but they are fewer than in Collembola. The tentorium is thus described by Oudemans ('88, p. 186): "Die vorderen [Stützplatten] kommen von den Seiten des Clypeus, gleich oberhalb der Mahlhöhle, wie dieses im Durchschnitt abgebildet ist in Figur 32. Links und rechts geht dort die Chitinhaut des Clypeus über in eine Platte. Die beiden Platten nähern sich nach hinten, indem sie fortwährend breiter werden. In der Mitte des Kopfes kommen sie zusammen, sind da jedoch nicht verschmolzen, sondern nur stark durch Bindegewebe verbunden, Figur 19 L¹. Hinter dieser Verbindungsstelle weichen die Platten wieder auseinander, werden schmaler und gehen, links und rechts vom Oesophagus, nach oben. Zuletzt geht jede über in einen

dünnen Chitinstab, welcher oben im Kopfe, hinter den Augen, endet und da am Chitin des Kopfes festsitzt."

Thus, the tentorium of *Machilis* is constructed upon the same plan as that of *Anurida*, although the median plate is halved longitudinally. The dorsal and posterior arms in *Anurida* are clearly represented in *Machilis*, and the latter pair tends to become reduced in size, — an approach to the Orthopteran condition.

The tentorium in Orthoptera is readily comparable with that of *Machilis*. In *Periplaneta*, according to Miall and Denny ('86, p. 39), "In front it gives off two long crura, or props, which pass to the ginglymus, and are reflected thence upon the inner surface of the clypeus, ascending as high as the antennary socket, round which they form a kind of rim. Each crus is twisted, so that the front surface becomes first internal and then posterior as it passes towards the clypeus. The form of the tentorium is in other respects readily understood from the figure (Figure 17). Its lower surface is strengthened by a median keel which gives attachment to muscles. The œsophagus passes upwards between the anterior crura, the long flexor of the mandible lies on each side of the central plate; the supraœsophageal ganglion rests on the plate above, and the subœsophageal ganglion lies below it, the nerve-cords which unite the two passing through the circular aperture. A similar internal chitinous skeleton occurs in the heads of other Orthoptera, as well as in Neuroptera and Lepidoptera."

In *Anabrus* (Packard, '98, p. 49, Figure 33) the tentorium is essentially the same, with a central plate, and paired dorsal and posterior arms. The only important differences between Orthoptera and *Collembola* in respect to the tentorium are (1) that the œsophageal commissures pass through it in the former group instead of around it; (2) that in Orthoptera the posterior arms are reduced in length, and (3) that the tentorium becomes more stoutly chitinized. On the other hand, the tentorium of Orthoptera, in its general form and topographical relations, agrees closely with the same structure in *Collembola* and *Thysanura*.

Palmén ('77) derived the tentorium from a pair of cephalic tracheæ in *Ephemera*, but upon unsatisfactory grounds. In *Collembola* tracheæ are absent; moreover, as Packard ('98, p. 50) notes, "the apodemes of the thoracic region are evidently not modified tracheæ, since the stigmata and tracheæ are present."

The views of Carrière ('90) and Cholodkowsky ('91), agreeing with the opinion of Palmén, have been controverted by Heymons ('95^b, pp. 50–51).

Wheeler ('89, p. 568) finds that five pairs of ectodermal invaginations form the tentorium of the larval head of *Doryphora*. "These invaginations grow inwards as slender tubes, which anastomose in some places. Their lumina are ultimately filled with chitin." Wheeler offers his observations in support of Palmén's theory, but they are not at all inharmonious with the scanty observations I have made upon *Anurida*.

Heymons ('95^b, pp. 50–51), describing *Forficula*, agrees with Wheeler, except that he finds only two pairs of fundaments for the tentorium, and says (p. 51): "Ich habe mich indessen davon überzeugt, dass auch bei *Gryllus* und *Periplaneta* die zahl der Tentoriumanlagen keine grössere ist, sondern, wie Heider ('89) dies bei *Hydrophilus* beschrieb, und ich es bei *Forficula* fand, nur vier beträgt. Der oben geschilderte Entwicklungsmodus des Tentoriums dürfte daher wohl als der typische anzusehen sein."

In *Anurida* I was unable to find any distinct ectodermal invaginations which might form the arms of the tentorium, but am not prepared to say that none exist, because the subject is one of great difficulty. The arms must be studied in oblique sections, and it is almost impossible to distinguish them from fundaments of muscles until they are nearly completed. The finished tentorium of *Collembola*, however, is undoubtedly homologous with that of *Thysanura*, and almost as clearly with the tentorium of *Orthoptera*.

Segmentation of the Head.

The elucidation of the primitive segments in Arthropods is a most interesting and difficult morphological problem. The rule of Savigny, — emphasized by Huxley and others, — that Arthropods consist fundamentally of successive rings, each of which may bear but one pair of primary appendages, although now undoubted, has never been thoroughly substantiated when applied to the Hexapod head. After years of argument, morphologists still disagree as to the number of somites composing the highly differentiated heads of insects. Kolbe ('90, p. 135) recognizes five, as follows: —

1. Ursegment: Fühler, Augen, Oberlippe;
2. Ursegment: Oberkiefer oder Mandibeln (1. Kiefernpaar);
3. Ursegment: Unterkiefer oder Maxillen (2. Kiefernpaar);
4. Ursegment: Zunge oder Innenlippe (3. Kiefernpaar, verwachsen);
5. Ursegment: Unterlippe (4. Kiefernpaar, verwachsen).

Sharp ('95, p. 87) says, "Morphologists are not yet agreed as to their

number, some thinking this is three, while others place it as high as seven; three or four being, perhaps, the figures at present most in favor, though Viallanes, who has recently discussed the subject, considers six, the number suggested by Huxley, as the most probable. Cholodkowsky is of a similar opinion."

Packard ('98, p. 54) gives six:—

	NAME OR SEGMENT.	PIECES OR REGIONS OF THE HEAD-CAPSULE.	APPENDAGES, ETC.
<i>Pre-oral in early embryo.</i>	1. Ocellar (Protocerebral).	Epicranium, anterior region with the clypeus, labrum, and epipharynx.	Compound and simple eyes (ocelli).
<i>Post-oral in early embryo.</i>	2. Antennal (Deutocerebral).	Epicranium, including the antennal sockets.	Antennæ.
	3. Premandibular, or Intercalary (Tritocerebral).	Wanting in post-embryonic life, except in Campodea.	Premandibular appendages (in Campodea).
	4. Mandibular.	Epicranium behind the antennæ, genæ.	Mandibles.
	5. First Maxillary.	Epicranium, hinder edge of tentorium.	First maxillæ.
	6. Second Maxillary, or labial.	Occiput.	Second maxillæ, or labium. Postgula, gula, submentum, mentum, hypopharynx (lingua, ligula), paraglossæ, spinneret.

Upon anatomical grounds, different observers have recognized from one to seven head segments. As mentioned by Packard ('98, p. 50), Burmeister found but two; Carus and Audouin three; MacLeay, Newman, and Newport four; Straus-Durekheim seven. Huxley ('78, p. 343) said: "It is hardly open to doubt that the mandibles, the maxillæ, and the labium answer to the mandibles and the two pairs of maxillæ of the crustacean mouth. In this case, one pair of antennary organs found in the latter is wanting in insects, as in other air-breathing Arthropods, and the existence of the corresponding somite cannot be proved. But if it be supposed to be present, though without any appendage, and if the

eyes be taken to represent the appendages of another somite, the insect-head will contain six somites." . . .

Huxley's conclusions were the most satisfactory that could be derived from a study of the completed organs alone, and reduced the problem to these questions: Do the eyes represent a somite? Is another antennal segment represented in insects? Do the labrum and hypopharynx represent distinct segments?

Authors began to realize the impossibility of settling the problem upon purely anatomical data, and attacked it from the embryological side.

Packard ('71, p. 21) concluded, "Accordingly, we seem forced to the belief that the head of the hexapodous insects consists of but *four* segments, *i. e.* the second maxillary, first maxillary, and mandibular segments, situated behind the mouth opening, and the antennary, or first and pre-oral segment, situated in front of the mouth. . . . The clypeus and labrum are apparently differentiated from the cephalic lobes, and thus seem to form a portion, or fold, of the antennary segment." Graber ('79) reached the same conclusion.

Viallanes, after carefully studying the development of the nervous system in Insects and decapod Crustacea, wrote the most important contribution upon the subject that has yet been published, and gave his results as follows ('87, pp. 108-109):—

"1. Le cerveau des Insectes, comme le cerveau des Crustacés décapodes, est formé de trois segments: j'appelle le premier *protocérébron* (cerveau du premier zoonite); le deuxième, *deutocérébron* (cerveau du deuxième zoonite); le troisième, *tritocérébron* (cerveau du troisième zoonite).

"2. Nous retrouvons, dans le protocérébron de l'Insecte, toutes les parties constitutives du protocérébron du Crustacé. Dans cette première région cérébrale, la seule différence qui s'observe entre les deux types est la suivante: chez l'Insecte les deux lobes protocérébraux viennent se souder sur la ligne médiane et se mettre ainsi en contact avec le protocérébron moyen. Chez le Crustacé, au contraire, les lobes protocérébraux sont très écartés de la ligne médiane et logés dans les pédoncules oculifères. Le rapprochement qui, chez l'Insecte, s'effectue entre les lobes protocérébraux, entraîne la disparition, ou pour mieux dire le raccourcissement extrême du tractus nerveux connu chez les Crustacés sous le nom de nerf optique.

"3. La deutocérébron, qui a une structure extrêmement caractéristique, se retrouve chez l'Insecte et chez le Crustacé avec les mêmes caractères et les mêmes connexions. Il en résulte que le nerf *antennaire* de l'Insecte est l'homologue du nerf de l'*antennule* du Crustacé.

"4. Chez le Crustacé le tritocérébron se compose des deux lobes antennaires et des deux ganglions œsophagiens (improprement appelés mandibulaires) et d'une commissure *sous-œsophagienne* (la commissure transverse de l'anneau

œsophagien) qui réunit ces derniers. Le lobe antennaire donne naissance au nerf de l'antenne externe, le ganglion œsophagien à la racine du premier ganglion viscéral impair (ganglion stomatogastrique) et au nerf du labre.

"Chez l'Insecte, le tritocérébron subit une importante réduction, les lobes et les nerfs antennaires disparaissent, mais les représentants des ganglions œsophagiens (que j'ai décrits sous le nom des lobes tritocérébraux) subsistent dans leur intégrité. Comme chez le Crustacé, ils donnent naissance à la racine du premier ganglion viscéral impair (ganglion frontal) et au nerf du labre ; comme chez les Crustacés, ils sont unis l'un à l'autre par une commissure *sous-œsophagienne* (commissure transverse de l'anneau œsophagien). Ainsi :

"Le nerf de l'antenne externe du Crustacé n'est pas représenté chez l'Insecte.

"Le nerf du *labre* de l'Insecte est l'homologue du nerf du *labre* du Crustacé."

After a lengthy discussion of the segmentation of the head, Viallanes concludes ('87, pp. 117-118) : —

"1. La tête de l'Insecte est formée par six zoonites, trois sont pré-buccaux et trois post-buccaux.

"2. Le premier zoonite porte les yeux composés et les ocelles. Le deuxième les antennes. Le troisième, *qui est dépourvu d'appendices*, porte le labre, pièce qui, pas plus chez les Insectes que chez les Crustacés, ne peut être considérée comme le résultat de la soudure de deux appendices.

"3. Le quatrième zoonite porte les mandibules, le cinquième les mâchoires, le sixième la lèvre inférieure."

Wheeler ('93), Heymons ('95), and others have confirmed these conclusions.

Heymons ('95^a, p. 36), in a valuable paper on the segmentation of the insect-body, says, "Der Kopf besteht aus sechs Körperabschnitten : dem Oralstück, Antennensegment, Vorkiefersegment, und drei Kiefersegmenten."

Rudimentary intercalary appendages have been found in *Anurida* (Wheeler, '93) and *Campodea* (Uzel, '97^b). Claypole ('98) and Uzel ('98) have homologized them with the second antennæ of Crustacea.

Six somites are the most that have been admitted upon embryological grounds, but I am convinced that there are more than six.

Hansen ('93) suggested that the so-called "paraglossæ" [superlinguæ] of *Machilis* were homologous with the Crustacean first maxillæ, and my observations upon the development of the superlinguæ support his view. The superlinguæ originate independently as a pair of simple papillæ — like the mandibles and maxillæ — intermediate between the mandibles and the "first maxillæ," and represent a distinct, though reduced, seg-

ment, because provided with a ganglion. More conclusive proof could hardly be expected.

The insect-head, then, is composed of seven somites, which are homologous with the first seven of decapod Crustacea.

If the conclusions I have drawn in this paper are valid, certain radical changes become necessary in the commonly accepted ideas of homology among the great classes of Arthropods. These changes I submit in the following table:—

TABLE OF EQUIVALENT SOMITES IN THE HEAD OF ARTHROPODA.

<i>Segment</i>	<i>Arachnida</i>	<i>Chilopoda</i>	<i>Diplopoda</i>	<i>Crustacea</i>	<i>Hexapoda</i>
1	Compound eyes and ocelli	Compound eyes and ocelli
2	Embryonic præantennæ.	First antennæ	Antennæ
3	Antennæ	Antennæ	Second antennæ	Intercalary appendages
4	Chelicerae	Mandibles	Mandibles	Mandibles	Mandibles
5	Pedipalpi	First maxillæ	Gnathochilarium	First maxillæ	Superlinguæ
6	First legs	Second maxillæ		Second maxillæ	Maxillæ
7	Second legs	Maxillipedes		First maxillipedes	Labium

Summary.

The protocerebrum of Apterygota agrees with that of other insects in development and structure. The ocular segments of Hexapoda and decapod Crustacea, as well as the compound eyes of the two groups, are homologous.

The labrum and clypeus of insects develop from a single median evagination between the procephalic lobes, and do not represent a pair of appendages. The labrum of Apterygota is homologous with that of other insects, as well as that of Symphyla, Diplopoda, Chilopoda, and the higher Crustacea.

The antennæ of Apterygota evaginate from the posterior boundaries of the procephalic lobes, and therefore agree with those of Pterygota in this respect. In both groups the antennæ are at first post-oral and subsequently pre-oral in position.

The deutocerebrum of insects is homologous with that of Crustacea, and the antennæ of Hexapoda are equivalent to the antennules of Crustacea and the embryonic præantennæ of Chilopoda.

Premandibular, or intercalary, appendages exist in the embryo of Anurida, and appear to be represented even in the adults of several Apterygote genera. The tritocerebrum of Apterygota is homologous with that of Orthoptera and decapod Crustacea, and the rudimentary premandibular appendages of Collembola and Thysanura represent the second antennæ of decapod Crustacea and probably the antennæ of Diplopoda and Chilopoda. A distinct primitive ganglion occurs in the intercalary segment of Anurida, therefore the segment must be regarded as one of the primary head-segments.

The mandibles of Apterygota develop from a pair of simple papillæ, the bases of which become oblique. No trace of lobation occurs except in Campodea. The mandibles of Collembola and Thysanura are homodynamous with the maxillæ and homologous with the mandibles of Pterygota, Scolopendrella, Crustacea, and probably Diplopoda and Chilopoda.

The "hypopharynx" in Apterygota is a compound structure consisting of two dorsal "superlinguæ," — as I have called them, — which develop from a pair of papillæ between the mandibular and first maxillary segments, and also a ventral lingua, which originates independently as a median unpaired evagination on the first maxillary segment. The two chitinous "lingual stalks," which are most highly developed among Apterygota, arise in superficial grooves of the ectoderm. The hypopharynx of Apterygota is undoubtedly homologous with that of Pterygota; although, in the latter group, the lingua and superlinguæ become united together and the lingual stalks become rudimentary. In Anurida a distinct neuromere exists for the "superlinguæ;" therefore it is necessary to recognize the superlingual segment as equivalent in morphological value to the other primary somites. The superlinguæ are homologous with the first maxillæ of Malacostraca and Chilopoda and are anatomically represented in the labial plate of Diplopoda. In order to avoid confusion, the terms "paraglossæ" and "ligula" should not be applied to the constituents of the hypopharynx, but are better restricted to the labium of insects. The lingua of Hexapoda is equivalent to the Crusta-

cean hypopharynx, and possibly also to the median component of the Diplopod gnathochilarium.

The first maxillæ in Collembola and Thysanura develop essentially as in Orthoptera and may be homologized part for part with the maxillæ of generalized Pterygota. In Anurida a palpus appears in the embryo, but is resorbed before hatching, indicating the derivation of this genus from a form in which the first maxillary palpi were functional, as they are at present in Orchesella, Tomocerus, and other Collembolan genera. The first maxillæ of Campodea are clearly to be homologized with the first of Scolopendrella, the second of Chilopoda, and less clearly with the lateral portions of the Diplopod gnathochilarium. The first maxillæ of insects pass through a biramous condition, as in Crustacea, and the sclerites of these organs appear to be homologous in the two groups; the first maxillæ of Hexapoda, however, are equivalent to the second maxillæ of Malacostraca.

The labium in Anurida develops from a pair of papillæ, from which the entire gular region is derived. A palpus appears, but is soon resorbed, and no galeal and lacinial lobes are differentiated. Upon the whole, the labium among Apterygota is homologous with the same structure of Pterygota, although fewer sclerites are formed in the former group. The labium in insects, homodynamous with the mandibles and first maxillæ, agrees in detail with the first maxillipedes of decapod Crustacea. The labium of Campodea is homologous with the "second maxillæ" of Scolopendrella and the maxillipeds of Chilopoda, and is represented in the gnathochilarium of Diplopoda.

The sides of the face in Anurida develop from two lateral evaginations of the germ band near the mandibular segment, which eventually involve the labral and labial fundaments and complete the buccal cone. The mouth-folds of Collembola, Campodea, and Japyx are strictly homologous with the genæ of Pterygota. The dorsal region of the skull in Anurida does not differentiate into sclerites which may be compared with those of Pterygote insects.

The tentorium is inferred to develop from cells which have been proliferated from the ectoderm.

The evidence convinces me that there are just seven somites in the head of Anurida, and that probably the same is true for all Hexapoda. The cephalic somites are successively: ocular, antennal, intercalary, mandibular, superlingual, maxillary, and labial. As I have found embryonic ganglia for the intercalary and superlingual segments, there are seven cephalic ganglia, one for each somite. Moreover, excepting

the ocular segment, every somite is represented by a pair of appendages. I find no evidence whatever for more than seven primitive cephalic segments, and believe that my observations have assisted to settle the long-disputed question of the segmentation of the head.

Since the time of Fabricius, the mouth-parts of insects have been of primary importance for the systematist. While insisting that a logical classification must recognize *all* anatomical structures, it must be admitted that the mouth-parts are of fundamental systematic value on account of the range of their differentiation.

Without discussing at length the phylogeny of insects, I may briefly give the bearing of these studies upon the subject, remarking that my conclusions are in entire accord with approved views upon the origin of insects.

The Collembola are strikingly like Campodea and Japyx in structure, their peculiar entognathous characteristic separating these three groups from all other insects. The Collembola as a group are somewhat more specialized than the Thysanura in general structure. The Smynthuridæ, with their globular bodies, vertical heads, and well-developed furculæ and ventral tubes, represent one extreme of differentiation — comparatively high. The Aphoruridæ, including Anurida, with vermiform bodies, subequal segments, horizontal heads, no furcula, etc., are much more generalized, and probably degenerate forms. Anurida, for example, has both pairs of maxillary palpi, as well as rudimentary abdominal appendages and the fundamentals of a furcula in the embryo, but in the embryo only. Therefore the ancestral Collembolan was probably intermediate between Smynthuridæ and Aphoruridæ, and is most nearly represented by members of the family Poduridæ. The resemblance in the mouth-parts leads us to suppose that the primitive Collembolan descended from the stem form of Campodea and not far below Campodea itself.

The affinities of Campodea, which is slightly more primitive than Japyx, are in two directions: towards Machilis and Lepisma on the one hand, and towards Scolopendrella on the other. In the first two genera the mouth-parts are clearly derivable from the Campodean type, and link Campodea with Orthoptera. In regard to Scolopendrella, it was long uncertain whether it should be placed among Thysanura or Myriopoda, on account of its strong affinities for both. Most authors have followed Grassi and placed it in the latter group, always admitting its insectean features. In the mouth-parts, Scolopendrella approaches

Campodea rather than Diplopoda, but is unquestionably nearer Diplopoda than it is to Chilopoda.

The gnathochilarium of Diplopoda may be homologized with the appendages of three hexapod somites, but only two embryonic segments have as yet been found; and the subject needs further investigation.

The mouth-parts of Chilopoda may be homologized with those of insects in only the broadest way, the correspondences being principally those of position.

Between decapod Crustacea and Apterygota there are decided morphological resemblances. The seven cephalic somites which I have found in the latter group I have homologized in detail with the anterior seven of the former, and pointed out that most of the homologous appendages function alike in the two groups. These homologies, however, simply indicate a partial parallelism in development; for in most respects Crustacea and Hexapoda are very divergent classes.

PUBLICATIONS
OF THE
MUSEUM OF COMPARATIVE ZOÖLOGY
AT HARVARD COLLEGE.

There have been published of the BULLETINS Vols. I. to XXXV.; of the Memoirs, Vols. I. to XXIV.

Vols. XXXVI., XXXVII., and XXXVIII. of the BULLETIN, and Vols. XXV., XXVI. of the MEMOIRS, are now in course of publication.

The BULLETIN and MEMOIRS are devoted to the publication of original work by the Professors and Assistants of the Museum, of investigations carried on by students and others in the different Laboratories of Natural History, and of work by specialists based upon the Museum Collections and Explorations.

The following publications are in preparation:—

Reports on the Results of Dredging Operations from 1877 to 1880, in charge of Alexander Agassiz, by the U. S. Coast Survey Steamer "Blake," Lieut. Commander C. D. Sigsbee, U. S. N., and Commander J. R. Bartlett, U. S. N., Commanding.

Reports on the Results of the Expedition of 1891 of the U. S. Fish Commission Steamer "Albatross," Lieut. Commander Z. L. Tanner, U. S. N., Commanding, in charge of Alexander Agassiz.

Reports on the Scientific Results of the Expedition to the Tropical Pacific, in charge of Alexander Agassiz, on the U. S. Fish Commission Steamer "Albatross," from August, 1899, to March, 1900, Commander Jefferson F. Moser, U. S. N., Commanding.

Contributions from the Zoölogical Laboratory, in charge of Professor E. L. Mark.

Contributions from the Geological Laboratory, in charge of Professor N. S. Shaler.

Subscriptions for the publications of the Museum will be received on the following terms:—

For the BULLETIN, \$4.00 per volume, payable in advance.

For the MEMOIRS, \$8.00 " " "

These publications are issued in numbers at irregular intervals; one volume of the Bulletin (8vo) and half a volume of the Memoirs (4to) usually appear annually. Each number of the Bulletin and of the Memoirs is also sold separately. A price list of the publications of the Museum will be sent on application to the Librarian of the Museum of Comparative Zoölogy, Cambridge, Mass.

No. 6. — *Report on the Dredging Operations off the West Coast of Central America to the Galapagos, to the West Coast of Mexico, and in the Gulf of California, in charge of Alexander Agassiz, carried on by the U. S. Fish Commission Steamer "Albatross," during 1891, LIEUT. COMMANDER Z. L. TANNER, U. S. N., Commanding.*

XXVIII.

Description of two new Lizards of the genus Anolis from Cocos and Malpelo Islands. BY LEONHARD STEJNEGER.

The two Anoles here described were the only reptiles obtained on the islands of Cocos and Malpelo during the expedition. Each species is peculiar to the island upon which it is found. Of the two, the one from Malpelo seems to be most highly specialized, there being no nearly related species on the mainland with which I am familiar, while the species from Cocos Island belongs to a group which has a number of representatives in Central America. The two species are only distantly interrelated, inasmuch as they belong to widely separated sections of the genus.

It is quite possible that a more thorough search on Cocos Island might reveal additional reptiles. In fact, Mr. Townsend informs me that he saw a snake there which escaped.

*Anolis agassizi*¹ sp. nov.

Diagnosis.—Tail cylindrical, without crest or keel; dorsal scales keeled, subequal to those on the flanks, slightly smaller than the ventrals, and separated from each other by one or more rows of minute granules; ventral scales keeled; digital expansions very large; about thirty-six transverse lamellæ under ii and iii phalanges of fourth toe; occipital scale about as large as ear-opening; scales of supraorbital semicircles very much enlarged (forming high, tuberculated crests in the adults), and separated by one row of small scales; occipital separated from supraorbital semicircles by one or two series of scales; supraocular scales rough or rugose, sometimes irregularly keeled; canthus rostralis sharp; mental shield single, with a deep sulcus posteriorly, very large; tibia nearly equalling the head in length, and at

¹ Named in honor of Professor Alexander Agassiz.

least as long as distance from mouth to ear-opening; scales on under side of tail twice as large as those on the upper side, all keeled; scales on dorsal surface of hands and feet multi-carinate. Adults with a high longitudinal cervico-nuchal flap; males with enlarged post-anal scales.

Habitat. — Malpelo Island, Pacific Ocean, off Columbia, South America.

Type. — U. S. National Museum, No 22101; March 5, 1891; collector, Chas. H. Townsend.

Description. — ♂ ad. U. S. Nat. Mus. No. 22101. Head once and two thirds as long as broad, slightly longer than tibia; frontal and occipital regions deeply concave; supraorbital ridges high, bony, surrounding the occipital hollow, and nearly joining behind it at the beginning of the cervico-nuchal fold; anteriorly they divide and continue mesially as frontal ridges which converge on the snout, meeting some distance behind the level of the nostrils, while externally they join the supraciliary ridge, and in company the latter extend to under the nostrils as a strong canthus rostralis, thus forming a deep valley on each side between the canthus and the frontal ridge; there is also a post-superciliary ridge extending to above the ear-opening, and with a valley between it and the occipital ridge; scales of supraorbital semicircles very much enlarged, forming high tuberculated bony crests, separated by a single series of very small scales; scales forming frontal ridges and valleys rather large, irregularly hexagonal, concave or convex according to situation; scales on snout smaller, more irregular, elongate, four in contact with rostral; about seven larger supraocular scales, keeled or tuberculated, separated by one row of granules from semicirculars; superciliary edge with two very elongated scales anteriorly, granular posteriorly; occipital scale slightly larger than ear-opening, separated from supraorbital semicircle by one row of scales; three canthal scales; loreal region with two deep hollows, the posterior one largest; loreal rows four; a series of large suboculars, of which the one below the posterior angle of the eye descends to the edge of the lip; rostral very wide and very low, four times as wide as high, nearly rectangular; six to seven low supralabials in front of the subocular edging the lip, decreasing in height posteriorly; ear-opening rather small, oval, vertically oblique; nape and neck with a high, flexible dermal crest or flap on the middle line, almost co-extensive with the poorly developed dewlap underneath; several dermal folds and wrinkles on sides of neck; mental shield large, with a deep sulcus behind; gular scales small, feebly keeled; body feebly compressed; dorsal scales slightly larger than those on flanks, a few series along the median line decidedly, though not abruptly larger, all more or less distinctly keeled and surrounded by one or more minute granules; ventral scales slightly larger than dorsals, rhomboidal, imbricate, keeled, about five to six in the distance between nostrils; scales on anterior surfaces of limbs larger than ventrals, keeled, those on dorsal surface of hands and feet multi-carinate; adpressed hind limb reaches halfway between eye and nostral; digital expansions very large, thirty-six transverse lamellæ under ii and iii phalanges of fourth toe; tail less than twice the length of head and body, cylindrical, without crest or keel; scales on tail larger than ventrals, straight, in transverse rows, but with

scarcely an indication of verticels, those on the lower surface nearly twice as large as those above; a pair of enlarged post-anal scales. Color of live specimen (according to the sketch of Mr. Magnus Westergren, the artist of the expedition): top and sides of head and neck uniform sooty black gradually merging into the ground color of the upper surface of body, which is "Vandyke" brown, sprinkled with minute dots of an ochraceous buff; upper surface of limbs as well as alternate cross-bands on tail similarly colored; the hands and feet as well as the intervals between the crossbands pale "Nile" blue; end of snout, lips, and entire under side similarly bluish white. In alcohol the ground color is more blackish and the dots less yellowish.

DIMENSIONS.

Total length	271 mm.
Snout to ear-opening	26 "
Snout to vent	101 "
Tail from vent	170 "
Fore limb	50 "
Hind limb	90 "
Tibia	26 "

Variation.—A large full-grown female (No. 22103) differs from the male described above only in the absence of enlarged post-anal scales. Two somewhat younger specimens (female, No. 22104, male, No. 22105) differ from the fully adult specimens chiefly in the lesser elevation of the cephalic crests and the total absence of the cervico-nuchal flap; the color of the back, which seems to be identical with that of the adults, extends also over the upper surface of neck and head.

Remarks.—Mr. Charles H. Townsend, who collected these specimens in Malpelo, informs me that they were running over the rocks near the water. The island was too steep to afford a landing, but the lizards were shot off or whisked off the face of the cliffs, thus falling into the water, whence they were secured by the collector.

Anolis townsendi,¹ sp. nov.

Diagnosis.—Tail subcylindrical; dorsal scales but indistinctly larger than those on the flanks, those on the vertebral region keeled; gular and ventral scales keeled; digital expansion strongly developed; occipital scale larger than ear-opening, separated from supraorbital semicircles by two or three scales, the semicircles separated by a similar number of scales; scales on upper surface of snout as well as enlarged supraoculars keeled; anterior half of superciliary ridge with three very long and narrow, strongly keeled scales placed obliquely; no markedly enlarged series of scales below infralabials; tibia measuring more than two thirds the length of head, slightly shorter than distance between end of snout and ear-opening; the adpressed hind limb reaches beyond the eye; tail more than once and a half as long as head and body.

¹ Named in honor of Mr. Charles H. Townsend.

Habitat. — Cocos Island, Pacific Ocean, off Costa Rica, Central America.

Type. — U. S. National Museum, No. 22106; Feb. 28, 1891; collector, Charles H. Townsend.

Description. — ♂ ad. U. S. Nat. Mus. No. 22106. Head twice as long as broad, longer than tibia; forehead slightly concave; frontal ridges nearly obsolete; upper head scales small, keeled; scales of supraorbital semicircles moderately enlarged, separated by three scales; enlarged supraorbitals numerous, elongated, sharply keeled, in contact with semicirculars; occipital shield elongate oblong, somewhat larger than ear-opening, separated from semicirculars by two scales; canthus rostralis very distinct, of six scales, the anterior ones small, the posterior two very long and narrow continued backwards in line with three superciliaries, which are also unusually long, narrow, and keeled; posterior half of superciliary ridge granular; a series of enlarged suboculars, keeled, not reaching lip; loreal rows, about six, keeled; eight supralabials to below centre of eye, rugose; ear-opening moderate, vertically oval; dewlap moderate with a thickened edge of densely set short thick scales, those on sides of appendage distant and very elongate; gular scales small, long, and narrow; dorsal scales much smaller than ventrals, and indistinctly larger than those on the flanks, and gradually but slightly increasing in size toward the vertebral line, where a few rows are distinctly keeled; no dorsal or cervical fold or crest; ventral scales larger, imbricate, keeled, like all the scales of the underside; scales on anterior surfaces of limbs somewhat larger than ventrals, keeled; tail subcylindric, scales about the size of ventrals, keeled, with hardly an indication of verticils; body compressed; adpressed hind limb reaches beyond eye; no enlarged post-anal scales. Color above dull brownish gray, irregularly and indistinctly mottled with dusky which shows a tendency to form cross-bars on the tail; limbs more brownish with lighter roundish spots; lores, temples, and sides of neck anteriorly with irregular white markings; a very distinct white, black-edged lateral band from sides of neck over the shoulder to groin; underside whitish; throat with indistinct, brownish mottlings.

DIMENSIONS.

Total length	123 mm.
Snout to ear-opening	13 "
Snout to vent	47 "
Tail from vent	76 "
Fore limb	22 "
Hind limb	37 "
Tibia	12 "

Variation. — A slightly smaller female (U. S. Nat. Mus. No. 22107) differs chiefly in the absence of a dewlap and in coloration; the white lateral band is present, but it is not edged with blackish, and there is in addition a narrow white vertebral band from occiput to root of tail.

PUBLICATIONS
OF THE
MUSEUM OF COMPARATIVE ZOÖLOGY
AT HARVARD COLLEGE.

There have been published of the BULLETINS Vols. I. to XXXV.; of the MEMOIRS, Vols. I. to XXIV.

Vols. XXXVI., XXXVII., and XXXVIII. of the BULLETIN, and Vols. XXV., XXVI. of the MEMOIRS, are now in course of publication.

The BULLETIN and MEMOIRS are devoted to the publication of original work by the Professors and Assistants of the Museum, of investigations carried on by students and others in the different Laboratories of Natural History, and of work by specialists based upon the Museum Collections and Explorations.

The following publications are in preparation:—

Reports on the Results of Dredging Operations from 1877 to 1880, in charge of Alexander Agassiz, by the U. S. Coast Survey Steamer "Blake," Lieut. Commander C. D. Sigsbee, U. S. N., and Commander J. R. Bartlett, U. S. N., Commanding.

Reports on the Results of the Expedition of 1891 of the U. S. Fish Commission Steamer "Albatross," Lieut. Commander Z. L. Tanner, U. S. N., Commanding, in charge of Alexander Agassiz.

Reports on the Scientific Results of the Expedition to the Tropical Pacific, in charge of Alexander Agassiz, on the U. S. Fish Commission Steamer "Albatross," from August, 1899, to March, 1900, Commander Jefferson F. Moser, U. S. N., Commanding.

Contributions from the Zoölogical Laboratory, in charge of Professor E. L. Mark.

Contributions from the Geological Laboratory, in charge of Professor N. S. Shaler.

Subscriptions for the publications of the Museum will be received on the following terms:—

For the BULLETIN, \$4.00 per volume, payable in advance.

For the MEMOIRS, \$8.00 " " "

These publications are issued in numbers at irregular intervals; one volume of the Bulletin (8vo) and half a volume of the Memoirs (4to) usually appear annually. Each number of the Bulletin and of the Memoirs is also sold separately. A price list of the publications of the Museum will be sent on application to the Librarian of the Museum of Comparative Zoölogy, Cambridge, Mass.

INTRODUCTION.

SINCE the appearance of the admirable paper by Hensen ('63) on the auditory organs of decapods, a period of thirty-seven years has elapsed, a period rich in zoölogical discoveries and improvement in general technique. The great advances made in comparative neurology by means of modern methods have reopened to investigators fields for research hitherto considered exhausted. The zoölogist of the present time is thus enabled to reap a second crop on ground already carefully gleaned, and to harvest results as important as those originally obtained.

The physiological work of Hensen's paper has been continued in recent years by various investigators. But aside from the paper by Bethe ('95) on the otocysts¹ of the schizopod *Mysis*, little work has been done on the morphology of the decapod ear since 1863.

¹ Throughout this paper the terms otocyst, statocyst, ear, and auditory sac will be used synonymously to designate the auditory organ, so-called, of Crustacea.

To throw more light on our knowledge of the vertebrate ear, comparative study of the (perhaps) analogous organ found among invertebrates may be of great practical value. For by such comparative study zoölogists have been enabled to solve many perplexing questions which might otherwise have proved too difficult for solution.

The present study was undertaken with this practical bearing of the subject in mind, and with the hope that by the aid of modern neurological technique it would be possible to go deeper into many undecided questions than Hensen could.

The work is necessarily twofold in its scope, owing to the inseparable nature of the morphology and physiology of the auditory organ. We have, first, to obtain more accurate knowledge concerning the structure, innervation, and development of the decapod otocyst. In doing this especial attention must be given to the innervation, which must be compared with that of other sense organs in decapods. And, secondly, we must determine from evidence obtained by others in the past, and from additional physiological experiment, whether we are justified in ascribing a true auditory function to this much discussed apparatus.

PART I. — MORPHOLOGY.

A. HISTORICAL SURVEY.

Although the literature up to Hensen's time is well summarized by him, yet it may be worth the while to take a glance at what has been done, touching upon only the more important works, however, as a fairly complete list of authors is appended in the Bibliography.

The earliest notice of an ear in Crustacea is that of Minasi, a Dominican monk, who in 1775 attributed the sense of hearing to *Pagurus*, the hermit crab, and described as the auditory apparatus what is now known as the green gland or excretory organ of decapods. The organ supposed to subserve the function of hearing was thus from the very first misplaced, and its identity was in doubt even up to the time of Häckel ('57) and Leydig ('57), who were the first to rectify the erroneous ideas which existed in regard to the functions of the green gland and the otocyst.

The true sacs were, however, discovered and described as early as 1811 by Rosenthal ('11). He mentions the cavity, its opening, and nerve; but it was left for Treviranus ('02-'22, Bd. 6, pp. 308-310) to discover the sand, or otoliths, present in the otic chamber.

The first good description of the organ, accompanied by figures, was given by the Englishman Farre ('43), who carefully dissected the otocysts of the crayfish (*Astacus fluviatilis*), the European lobster (*Astacus marinus*), the hermit crab (*Pagurus*), and the rock lobster (*Palinurus quadricornis*).

The organs were found by Farre to be situated in the basal segment of the inner antennæ (antennules), the thin dorsal membrane of which in *A. marinus* he compared to the fenestra ovalis of the vertebrate ear. The openings of the sacs were always found to be large enough to admit the otoliths, which rest upon auditory bristles. The otoliths were, he maintained, merely grains of sand. The auditory bristles were briefly described, and their semi-circular arrangement noted; a nerve was traced from the brain to the ventral surface of the otocyst, where it formed a plexus. In Farre's opinion separate fibres probably supplied the bases of the different hairs. While the otocysts of the lobster, crayfish, and hermit crab were of relatively large size, nearly filling the basal segment of the antennule, their openings were very small and well guarded by a "chevaux de frise" of bristles. In *Palinurus* the organ was apparently degenerate; the sac small, shallow, with very large opening, and the auditory hairs sparse and irregularly arranged. The otoliths were of large size and few in number. The whole apparatus was held by Farre to be a delicately modified tactile organ, and he doubted if a *true auditory function* could be ascribed to it.

During the next twenty-five years otocysts were discovered and examined in various decapods by Souleyet ('43), Von Siebold ('44, '48), Leuckart ('53, '59), Frey und Leuckart ('47), Huxley ('51), Leydig ('55, '57, '60), Bate ('55, '58), Hensen ('63), Sars ('67), and Lemoine ('68). Leuckart und Frey ('47) briefly described the sacs which they found in the endopod of the last abdominal appendages of *Mysis*, mentioning the otolith and auditory hairs.

Leuckart ('53) made a comparative study of the otocysts in many crustacean forms. He divided them into two groups:—Those having (1) closed sacs with one otolith, and (2) open sacs with many otoliths. Leuckart's general descriptions agree with those of Farre.

Kroyer ('59) devotes a few pages of his monograph on *Sergestes* to a comparative account of this organ in different Crustacea. He follows Leuckart's method of grouping. To the first type (closed sacs, and one otolith) belong such forms as *Lucifer*, *Sergestes*, *Mysis*, and *Phyllosoma*. In the second group (open sacs and many otoliths) are placed *Homarus*, *Astacus*, and *Palinurus*. In the opinion of Kroyer, Farre erred in con-

sidering the otoliths simply particles of sand; for sometimes the sacs are closed, and again the openings are often too small to admit the passage of the otoliths from the exterior. They must be, then, deposits of calcium carbonate secreted by the animals themselves.

Hensen's ('63) account of the otocyst is far more complete than any other, and a fairly extensive review of his paper is necessary for the sake of later comparisons. He worked mostly with freshly collected animals, although some twenty-four species were studied from alcoholic material. His principal methods were dissection and maceration, some few crude sections, however, being made. The paper is divided into an anatomical and a physiological part. The latter portion will be reviewed, along with other papers of a similar nature, in Part II of this paper.

The elementary parts of the typical auditory organ are described by Hensen ('63, p. 326) thus: "Der Gehörapparat der höheren Krebse besteht nun, kurz gesagt, darin, dass, von der Endganglie eines Nerven ein feiner Faden in ein Chitinhaar hineintritt, und an einen eigenthümlich gebildeten Theil der Haarwand sich festsetzt. Diese Haarwand ist so locker mit der Schalenhaut verbunden, dass sie bei entsprechenden Tönen recht bedeutende Schwingungen vollführen kann und vollführt. Das Haar selbst geht zuweilen noch in oder zwischen Steine hinein."

Crustacea he divides into four classes according to the condition of otocyst and otoliths:—

1. Sacs closed, with one otolith: example, *Mysis*.
2. Sacs closed, without an otolith: all *Brachiura*.
3. Sacs open, many otoliths: *Astacus*, *Palæmon*.
4. No sac nor otoliths, but free auditory hairs.

Otoliths. In confirmation of Farre it was found that the otoliths of decapods having open ear sacs were mainly composed of grains of sand. This was proved by chemical tests, and by keeping newly moulted animals (*Palæmon*) in filtered water to which uric acid crystals had been added. Examination of the otocysts some time after moulting showed the presence of these crystals in the sac. In larger forms, such as the lobster and crayfish, the sand particles are spread over the whole basal surface of the ear sac. In shrimps and prawns they are more closely aggregated. The single otolith found in *Mysis flexuosus* is described at length, but as this account has been corrected by Bethe ('95), it will be referred to later in connection with Bethe's work.

The *Otocyst* (Hörblase of Hensen) is described in general as a round-

ish or ovoid cavity, lined with chitin; the opening, if any, is always dorsal, and varies greatly in size. It is found in the basal segment of the first antennæ of all decapods, and in the endopod of the sixth or last abdominal appendage of the schizopods. The sac is closed in the *Brachiura* and *Schizopoda*, but open in most *Macrura*. The otocysts of *Crangon*, *Palæmon*, *Hippolyte*, *Mysis*, and *Carcinus mænas* are described in more detail, but no good figures or sections are given.

Auditory Hairs or Bristles. Hensen gives the first and only good description of these. They differ from common tactile hairs in that the hair shaft is not directly connected with the wall of the sac, but a thin chitinous membrane intervenes, forming a small hollow sphere. It is this "spherical membrane" which allows the great freedom of movement necessary for the shaft in its response to sound vibrations. A peculiar process, the "lingula," projects from the inner wall of the base of the shaft into the spherical membrane, and to this the nerve fibre is attached. The hair shaft is generally plumed, as in tactile hairs, with delicate chitinous filaments.

In *A. marinus* the hairs are plumed and are nearly one millimetre in length. They are here very numerous, 468 having been counted in one case, and are arranged on the floor of the otocyst in four parallel semi-circular rows.

A. fluviatilis has a much smaller number of hairs, but the same general arrangement; *Crangon*, a row of only seven or eight; these are more attenuate than in either of the above forms, but are 0.75 mm. in length.

Palæmon antennarius has about 40 hairs, arranged in a half-oval or horseshoe shape, the break in the oval being posterior. The hairs themselves are peculiar in having their shafts bent at a sharp angle. The portion of the shaft above the bend is much longer and more attenuate than the basal part, and is also heavily plumed. These plumed ends project toward the centre of the horseshoe, and intertwine. Their length is about 100μ and their greatest diameter 3.8μ . The hairs of *Hippolyte* and *Mysis* strongly resemble those of *Palæmon*, but they are embedded in the single otolith and are therefore unplumed.

Carcinus mænas has about three hundred auditory hairs. They are grouped into three classes: — 1. Hook hairs (*Hakenhaare*): the shaft hooked and with a plumed tip, about thirty in number, 50μ long, similar to the otolith hairs of *Macrura*. 2. Thread hairs (*Fadenhaare*): long, filamentous, plumed at very tip, a single row of about 46, each 338μ long, 3μ in diameter. 3. Tuft hairs (*Gruppenhaare*): short, blunt, and unplumed, about 200 in number, occurring in a single large group.

Hensen also found on the appendages of some decapods free hairs which closely resembled auditory bristles, and are described as such by him. Crangon especially, which has few hairs in the otocyst, is supplied with many of these so-called "free auditory hairs." They are also numerous in Mysis and Palæmon.

Innervation of the Otocyst. In Palæmon Hensen traced the nerve of the first antenna from the brain. A large branch of this nerve runs to the ventral side of the otocyst, where the fibres separate, each enlarging into a ganglionic cell and then proceeding to the base of a hair. Each of these terminal fibres ("Chordæ" according to Hensen) then enters the pore beneath a hair, passes through the spherical membrane to the lingula, or process from the base of the hair shaft, and makes itself fast to this. In his own words (Hensen, '63, p. 368): "Dieser eigenthümliche Faden, den wir als Chorda bezeichnen, läuft eine kürzere oder längere Strecke weit bis zu einem Hörhaare hinfort, und geht durch die Mitte des Porenkanals und der Haarkugel bis zur Lingula hin, an die er sich festsetzt." Essentially the same conditions were found by Hensen in Carcinus mænas and in Mysis. He also found nerve fibres supplying the tactile bristles which are present on all parts of the decapod body.

Formation of New Hairs (Haarwechsel). New hairs are not formed inside the old, but beneath the chitinous wall; and instead of developing from a single matrix cell, as was supposed, Hensen found that each was the product of a great number of cells. A new layer of chitin is formed beneath the old, and *under* this new layer, but continuous with it, the new hairs are formed as double-walled (i. e. invaginated) tubes. The new chitin wall is compared to the hand of a glove. If the fingers of the glove be turned partially outside in, so as to leave only their tips projecting, the condition would represent that of the hair tubes just before the moulting of the old shell. The tips of the newly formed hairs become attached to the shaft of the old hair, into which they project some distance, and as the latter are detached at ecdysis, the new hairs are pulled out. Nerve fibres were found running into the very tips of the new hairs. Hensen's theory is, that at moulting, the old nerve fibre, becoming more highly refractive and resembling chitin, is, upon the detachment of the old hair, drawn out through the apex of the new one, and that before this event a new fibre is formed. This theory, however, is not easily reconcilable with his statement that the nerve fibres attach themselves to the lingula at the base of the hair shaft.

The remainder of this part of his paper is devoted to brief descriptions of the otocyst as found in some twenty-four different species of Crustacea.

To this is added a table, embracing all the forms which have been studied, giving the names of the different investigators, and the conditions, as to number and size, of both the auditory hairs proper (Otolithenhaare) and the "free auditory hairs" found on the antennæ and abdominal appendages.

Lemoine ('68) compares the otocyst of the lobster with that of the crayfish. His descriptions are similar to those of Farre ('43), but his figures are poor. The thin dorsal wall of the basal segment of the first antenna, which covers the ear sac, he calls the tympanic membrane of the lobster. The opening of the sac is overlooked, and the otocyst described as closed. Thus, as the otoliths cannot come from without, Lemoine's theory is that they are exfoliations from the calcified walls of the sac, — an absurdly impossible assumption, as the thin chitinous walls of the otocyst are not calcified. In the case of the crayfish, he notes nothing new except that there is a membrane at the base of each hair shaft, separating its cavity from that of the spherical enlargement on which the shaft stands. This membrane acts as an ear drum, taking the place of the large tympanic membrane described for the lobster.

Garbini ('80) discusses very briefly and incompletely the sense organs of *Palæmonetes varians*. The figures of the otocyst are extremely crude considering the date of the work, and simply confirm the conditions found by Hensen in *Palæmon*.

Vom Rath ('87, '88, '91, '94) does not make the sharp distinction between auditory and tactile hairs that Hensen does, holding that the two kinds grade insensibly into each other, the auditory hairs being simply slightly modified tactile organs. All sensory bristles of Crustacea can be divided into two chief groups: —

(1) Tactile or auditory hairs, with long, plumed shaft, the base of which is attached to the body wall by a delicate membrane of chitin, often spherical in form. Differentiation is thus towards freedom of movement in response to tactile or vibratile stimuli; (2) taste or olfactory hairs, having a short blunt shaft, thick-walled at the base, but with either a small pore or thin permeable membrane at its distal end, by means of which chemical substances in solution can come into direct contact with the nerve endings. The nervous apparatus of these hairs is the same in both cases for all decapods. The sweeping statement is made, that *beneath every sense hair there lies, either in the hypodermis, or removed some distance from it, a group of bipolar ganglion cells*. From each of these cells a fibre is given off peripherally, and these, *forming a strand, enter the base of the hair, ending only at its very tip*.

Claus ('75, '91) agrees with Vom Rath as to the nerve ending, but maintains that there is only *one* ganglion cell sending its process through a *group of matrix cells* into the hair. A misunderstanding as to the relations of the ganglion and matrix cells forms the basis of several controversial papers.

Retzius ('90, '92, '95) concludes in his last paper ('95) that there may be several ganglion cells to a single sensory hair. The number may indeed vary from one to many. He was unable by any method to trace the peripheral nerve fibres further than the base of the hairs. Nerve endings, which he described in his first paper ('90) as extending into the hair shaft, he afterwards ('92) frankly acknowledges to be artifacts.

Bethe ('95^a), in his admirable little paper on the otocysts of *Mysis*, clears up by modern methods many points, and corrects some of Hensen's erroneous descriptions. The sac in *Mysis* is ellipsoidal, and pointed posteriorly, while from its floor rises a sensory cushion bearing the hairs. This cushion is tilted outwards and ventralwards 45°, the right and left cushions thus being perpendicular to each other. The sac is open, not closed as described by Hensen; the narrow aperture is concealed by the overlapping walls of the otocyst. Borne on the sensory hairs is the large otolith, oval as seen from above, kidney-shaped in side view; its greatest diameter 0.3 mm., the other dimensions being 0.25 mm. and 0.15 mm. It is composed of a more or less organic core, about which concentric layers of calcium fluoride are deposited. The tips of the sensory hairs are embedded in this inorganic layer, and penetrate to the core of the otolith. The layers of calcium fluoride are probably deposited from the sea water. The sixty sensory hairs are arranged in a single row, so as to form two thirds of a circle, the break in the line being posterior and toward the median plane of the animal. At one end of the curve five hairs are grouped together, and at the other end there is an irregular double row. Though much like the auditory hairs of *Palæmon*, their tips, embedded in the otolith, are unplumed. Only *one ganglion cell* to a hair was found, sending a distal process into the base of each shaft. A double row of matrix cells lies just beneath the single row of hairs, and could easily be mistaken for ganglion cells. Vom Rath may have made this mistake, thus getting a multiganglion-celled condition for each hair.

The otocyst begins to develop before the appendage is fully formed. An invagination of the dorsal ectoderm takes place, producing a shallow depression; this enlarges while the opening gradually closes. Certain

of the hypodermis cells elongate to form the matrix cells which later produce auditory hairs. The latter are formed only after hatching.

Herrick ('95) mentions the auditory organ only in connection with the development of the lobster. The otocyst becomes prominent at the third larval stage, appearing as a shallow depression bordered with short setæ and containing a few grains of sand. The depression gradually enlarges, forming in the fifth stage a sac, the aperture of which decreases in size with successive moults, until the adult condition is attained.

Bethe ('95, '97) has traced the auditory fibres of *Carcinus mænas* centrally to the neuropil of the first antenna, where they end in delicate fibrillations. Some of these fibres may also end in the globulus.

From this review of the literature, it is seen that little has been done on the finer anatomy of the otocyst. Hensen's work, once considered exhaustive, will not suffice at the present time. The organ of *Brachyura* has not been touched upon since Hensen's dissections, while our knowledge as to the innervation of the different sensory hairs of Crustacea is left in a very hazy, confused state, since the exact condition of the peripheral endings is not firmly established, Claus, Vom Rath, Retzius, and Bethe each holding different views. The question remains unsettled as to whether the manner of innervation is the same for all the sensory hairs. G. H. Parker ('90) has clearly shown that the optic nerve in Crustacea is highly differentiated; but all the other sense organs have, according to Vom Rath, the same manner of innervation, even though they differ in function as much as the so-called auditory and olfactory bristles.

All the investigators of the crustacean otocyst, Bethe alone excepted, carried on their work under the impression that they were dealing with an auditory organ. This certainly prejudiced them in drawing conclusions. But for this, Hensen would never have likened the thickened wall of the crab's otocysts to the malleus of the vertebrate ear, nor made other far-fetched comparisons. A comparative study of the innervation of the otocyst, especially if supplemented by that of the olfactory and tactile bristles and the conditions in embryonic stages, cannot fail to clear up some of these questionable points.

B. OBSERVATIONS.

In the account of the morphology of the otocyst, two types will be taken for description:—

(1) *Open otocysts containing otoliths* (macruran decapods); the example will be *Palæmonetes vulgaris* Stimpson. The otocysts of the crayfish *Cambarus affinis* (Say) Girard, and of the prawn *Crangon vulgaris* Say, will be described in only sufficient detail to allow of comparison with *Palæmonetes*, and to correct any errors or omissions in the descriptions of other investigators.

(2) *Closed otocysts without otoliths* (brachyuran decapods); the sac of the green crab, *Carcinus mænas* Lin., will be taken as the example of this type.

For tracing out the *development* of the macruran otocyst (1), young lobsters were used instead of *Palæmonetes* larvæ, as it is difficult to obtain a complete series of the latter, and their small size makes them by no means favorable material for studying the embryology of the sac. Young lobsters, however, can be had in abundance during the hatching season, and are of large size; the otocyst is of the same general type as that of *Palæmonetes*. The development of the closed otocyst (2) was traced out in the crab for the sake of comparison with the macruran type of sac.

The research represented in this paper was carried on at the suggestion of Dr. E. L. Mark, to whom I wish here to express my thanks for his constant kindness, suggestive direction, and able criticism. I am also indebted for valuable supervision and helpful suggestions to Dr. G. H. Parker, who directed my work for one year during the absence of Dr. Mark.

1. Material.

Large numbers of *Palæmonetes* were obtained from the Charles River, Cambridge, at low tide. These river animals live well in either salt or fresh water, and may be kept in aquaria without running water for an indefinite period. Being so hardy, and at the same time free swimmers, they are eminently adapted for *intra vitam* stains, and for physiological experimentation.

Carcinus mænas was abundant in the soft-shelled condition, at Hadley Harbor, Naushon Id., during the months of June and July. The head of Great Harbor, Wood's Hole, was another good collecting ground.

Many soft-shelled animals were obtained by keeping young crabs in aquaria, and feeding them freely until ecdysis took place.

Lobster larvæ were hatched at the U. S. Fish Commission Station, Wood's Hole, during June and July. They were reared, but with great difficulty, up to the eighth moult. Fed on minced crab's liver they thrived well; but unfortunately they also fed indiscriminately on each other.

Crangon was found in large numbers in the muddy bottom of the Charles River; crayfish were bought in the New York City markets.

2. Methods.

In sectioning, great difficulty was experienced, both on account of the thickness of the chitin, which was often calcified, and because of the siliceous otoliths, so numerous in the sacs of *Macrura*, and glued by secretions to the hair tips. As the otoliths are insoluble in acids strong enough to completely destroy organic tissues, the only successful remedy was to remove them mechanically. This was best accomplished by washing them out by a stream of water blown into the sac. The apparatus for this consisted of a short piece of small rubber tubing into one end of which was inserted a glass tube drawn out to a fine point. The other end of the tubing being held in the mouth, and the capillary tube inserted into the aperture of the otocyst, a stream of water was driven into the cavity of the sac with considerable force. The larger otoliths having been washed out in this way, fairly good sections could be cut.

In the crab, the difficulty in cutting the very thick calcified chitin was obviated by using soft-shelled animals. The chitin is at this stage very thin, uncalcified, and therefore more readily sectioned. Lobster and crayfish antennules were decalcified by placing them in Gilson's fluid for twenty-four hours, or in Vom Rath's platinic-osmic fixative for a week or ten days.

Of the many fixing reagents used, (1) Vom Rath's platinic-osmo-picro-acetic mixture, (2) his corrosive-picro-acetic fluid, and (3) corrosive sublimate plus 1 % acetic acid gave the best results and in the order named. The last two were followed by staining in iron haematoxylin, which gave a clear definite stain of sections as thick as 20 μ . The platinic-chloride fixative of Vom Rath was used for from three to five days, either followed or not by treatment with pyroligneous acid. In *Palæmonetes* and *Crangon* a fine differentiation of fibre tracts was obtained by using

the fixative alone for three to five days, and washing out for at least two weeks in 90 % alcohol. The myelin sheath was intensely blackened, while all other tissues remained a yellowish brown.

For tracing nerve fibres, both to peripheral and central endings, *intra vitam* staining proved of most value. Different methods were employed for obtaining peripheral and central stains. A one per cent solution of methylen blue in normal NaCl was injected into the body in either case.

For peripheral endings several injections were made into the abdominal blood space, at intervals of thirty minutes. When the animals showed signs of stupefaction, a final injection was introduced into the pericardial chamber. The amount of solution injected varied from a few drops, in *Palæmonetes*, to five cubic centimetres, in the lobster. In from 15 to 30 minutes after the final injection the animals were usually dead. The part to be studied was then dissected out, barely covered with normal salt solution, and examined from time to time under the microscope, until a satisfactory degree of staining had been reached.

For central terminations one injection only was made, and this directly into the chamber of the heart, only a few drops of the solution being required. When the blue color was well diffused throughout the tissues (about one hour after injection), the brain was dissected out, or exposed, and examined as before. For fixation of the stain Bethe's ammonium-molybdate method for invertebrates was used. It was found to be better to leave preparations in xylol for only the shortest possible time, as this reagent diffuses the color. Preparations fixed by this method keep very well for a year or more, but after this they ultimately deteriorate, fibres originally sharp and continuous in outline becoming mere dotted lines, while the surrounding tissues take on a deep yellow hue. When both brain and otocyst were examined together, the peripheral cells and fibres stained first, then central fibres, central terminations, and ganglion cells of the brain in the order named. Sections 60-120 μ in thickness were cut, but by far the greater number of preparations were examined *in toto*. The transparency of the tissues made this possible even with the brains, a millimetre or more in thickness, of large crayfish.

To get constantly complete impregnations of both peripheral and central endings, it is necessary to expose to the atmosphere the part to be studied. The impregnation then takes place sooner, lasts longer, and affects a larger number of elements. The fixation of the color is also much better in this case, because the fluid can penetrate much more

readily, and on the rapidity of its penetration depends, in a large measure, the success of fixation. Gold-chloride and Golgi preparations were useful only for supplementing and controlling the results obtained by methylen blue. Both the rapid and slow processes for silver impregnations gave fairly good preparations, but by no means as complete or constant results as methylen blue. Ranvier's gold-chloride method, in which formic acid is used for reduction, was very uncertain in its action on nervous tissue, but was quite useful in bringing out fine cell processes in the sensory hairs.

3. Structure and Development.

I. PALEMONETES VULGARIS STIMPSON.

1. *Structure of the Otocyst.*

a. Sac. This is situated, as in all decapods except the Mysidæ, in the basal segment of the antennule, nearly filling its cavity. Its outline as seen from above (Plate 1, Fig. 1) is nearly ovate, being well rounded posteriorly, though suddenly becoming pointed at its anterior end. In individuals of medium size (30 mm. long) its average dimensions are 0.66 mm. in length, 0.63 mm. in width, and 0.33 mm. in depth. In longitudinal section (Plate 1, Fig. 4) its outline is somewhat kidney-shaped, its length being about twice its depth, and its ventral wall projecting into the lumen. Transverse sections through the basal portion of the antennule (Figs. 2, 3) show that the lumen of the otocyst is from one half to two thirds as wide as the antennule at this point. The chitinous wall of the sac, which is extremely thin, is continuous with that of the antennule (Fig. 3). The hypodermal cells form a single layer, except in the sensory region of the sac, where they are elongate and several layers thick. Median to the otocyst passes the antennular nerve, the cut end of which is shown at *n. at. 1* (Plate 1, Fig. 2), and directly below it lies the large muscle of the segment. Otoliths occupy the median and posterior portion of the lumen, and nearly conceal from view the sensory hairs (Fig. 3, *set. ot.*). In parasagittal sections (Fig. 4) is to be noticed the close proximity of the brain (*n' pil. opt.*), which is not more than 0.22 mm. posterior to the sac, and projects somewhat into the base of the antennule; the sensory cushion, or prominence (*crs. sns.*), bearing the stumps of a few severed hairs, is also to be seen.

The long axis of the otocyst is not coincident with that of the anten-

nule (Fig. 1), as its anterior end is more lateral in position than the posterior. The external aperture has the form of a pointed ellipse and penetrates the dorsal wall of the antennule; it is nearly as long as the sac itself, but does not extend quite as far back as the sac. It was described by some of the early writers as a longitudinal slit, by others as transverse; but, as Hensen points out, it is neither: its direction is oblique, and corresponds to that of the long axis of the otocyst. The opening is completely covered over by a thin fold of chitin (Figs. 1, 3, *tet.*), which extends forward and laterad to end in a sharp projection or spine. This lid-like fold (tectum) must be lifted or cut away in order to come directly at the opening of the otocyst. Figure 3 shows the position and form of the lid in transverse section, and how closely it fits over the aperture of the otocyst, while its forward projection over the anterior lip of the slit can be seen in Figure 5 (Plate 2) at *tet.* As the chitinous lining of the otocyst is of ectodermal origin, like all other chitinous parts, it is cast off at each ecdysis, with all it contains, and a newly secreted sac takes its place.

b. The sensory cushion of the otocyst is produced by an elevation of the median and posterior portion of the floor of the sac, which projects into the lumen and gives a somewhat constricted appearance to the cyst in sagittal sections. The surface of the cushion, which is about 0.25 mm. in diameter, is not horizontal, but slants downward from the median side of the sac to its lateral wall at an angle of nearly 45° (Plate 1, Fig. 3). This makes the sensory cushions of the right and left sides perpendicular to each other, a condition similar to that described for *Mysis* by Bethe ('95^a, p. 556), and of some physiological importance. The sensory hairs are borne on the sensory cushion, and for this reason the prominence has been compared to the *cristæ acusticæ* of vertebrates. The hairs, or bristles (for both names are applied to them), vary from forty-five to fifty-eight in number, and are arranged in a curved horse-shoe-like row (Plate 1, Fig. 1), the two ends of which are directed obliquely caudad and mediad. Largest at the inner end of the curve, and arranged in a single row, they grow gradually smaller toward the other end of the series, where an irregular double line is formed. Fig. 6 (Plate 2), a transverse section through the posterior ends of the horseshoe shows the base of a single hair on the right or median side, while at the left or lateral end two bristles are seen, the lateral row being double.

Directly beneath the hairs we find, instead of the usual layer of

hypodermal cells, groups of cells with elongated nuclei; these send their processes into the bases of the bristles (Plate 2, Figs. 6,7). They are the *matrix cells*, which nourish the hair and, as we shall see later, have to do with its formation. The central region beneath the cushion is occupied posteriorly by the ganglion cells of the otocyst nerve (Plate 2, Fig. 6, *cl. gn.*), and anteriorly by their peripheral fibres.

c. *Structure of hairs.* The hairs of the otocyst are peculiarly modified. Instead of being straight, as in tactile hairs, the shaft is here bent out of its course about 120° , so that its distal portion makes a sharp angle with the proximal end (Plate 2, Fig. 8). The shaft is very long in comparison with its diameter, being from 160μ to 200μ in length, while only 3 to 6μ in diameter at the base. The part of it above the bend becomes extremely attenuate, and is heavily fringed with long delicate projections (pinnules), which give it the appearance of a plume. These fine feathery tips, which always project toward the concave side of the horseshoe formed by their bases, are crisscrossed and tangled together in such a way as to form a wickerlike mesh, on which the majority of the otoliths rest (Plate 1, Fig. 3). The hairs are not attached firmly or immovably to the wall of the sensory cushion, but an exceedingly thin-walled chitinous bulb intervenes between the shaft and the wall of the sac. This, the *spherical membrane* of Hensen, is from 6 to 12μ in diameter, and allows the shaft, itself comparatively rigid, to sway freely on its base, as if articulated there (Plate 2, Fig. 8, *mb. sph.*).

d. *The formation of hairs* has already been described by Hensen ('63, p. 374) in some detail. The conditions just before ecdysis were figured, but the earlier stages were not given; so a few supplementary facts may be added here. Braun ('75) verified Hensen's account of *Haarwechsel* in the bristles of *Astacus*, and himself discovered some new details.

As before stated, each sensory hair is produced by a number of matrix cells, which send their processes into the shaft. In newly formed hairs, these protoplasmic processes extend to the very tip of the hair cavity (Plate 2, Fig. 7). In preparation for the next moult they are withdrawn nearly to the base of the hair, leaving the greater part of the hair cavity empty (Plate 2, Fig. 9). At the same time the matrix cells from which these processes are given off sink deeper into the tissue, below the level of the hypodermis, and with other chitinogenous cells originating in the hypodermis, arrange themselves about the nerve fibre of the

old bristle for the purpose of forming the new hair (Fig. 9, *cl. ma.*). This aggregation of cells is similar to the *papilla* described by Braun, but they are by no means as regular in outline and arrangement as those figured by him. In *Palæmonetes* this condition of the matrix cells exists for several weeks before ecdysis takes place, the new hairs being formed during this period. In adult lobsters and crayfish the time is probably much longer, whereas in larvæ it lasts but a few days. The chitin of the new hair shaft is secreted *pari passu* with that of the test, so that the two are continuous, but the new hair is *beneath* the shell, in the region where the matrix cells have formed the *papilla*. It is secreted as a double tube, the distal end of the inner part of which projects, as the tip of the new hair, into the base of the old one. Figure 10 (Plate 3) shows the condition of affairs just before ecdysis in the endopod of the third abdominal appendage; *cta.* being the old test, *cta'* the new one formed beneath it. Three newly formed hairs are seen as double tubes located deep in the appendage. The walls of the two tubes are continuous with each other at their lower or proximal ends, and the tip of the inner tube projects distally into the shaft of the old hair. This inner tube, the tip of the new hair, must be secreted by the delicate processes from the matrix cells which still extend up into the old hair during the period of hair formation. The outer tube, though continuous at its lower end with the inner, is secreted by two parallel rows of matrix cells, very similar to the chitinogenous cells of the hypodermis, and probably derived from them. Hensen ('63, p. 375) has well described this condition of the new hairs as resembling that of the finger of a glove turned partially inside out, the tips alone projecting. The tip of the new hair is embedded in a viscous, homogeneous substance, which is formed between the old and the new tests, either by glandular secretion of other cells or by the chitinogenous cells themselves. This substance probably corresponds to the homogeneous non-cellular membrane found by Herrick between the shells of the lobster ('95, p. 87). When the old test is shed, it adheres to the fine plumes of the new hair tip, and aided by the internal blood pressure (very considerable at the moulting period), draws the recently formed hair out into its functional position, just as one would draw out the invaginated finger of a glove by pulling on its tip. The chitin of the shaft is very soft and pliable at this time, allowing the hairs to be turned right side out with ease; indeed, this may be done artificially. But if by some accident at the time of ecdysis any of the hairs are not at once fully drawn out, the chitin hardens and they are fixed in their abnormal position.

Aside from its general interest, this peculiar method of forming the new hair is very important, as throwing light on the peripheral endings of the nerve fibres in the sensory hairs. By it certain conditions may be explained. At each moult the nerve fibres lose their connection with the old hairs, and come into relation with new ones. How these changes are brought about can best be described in connection with the innervation of the otocyst.

e. The Otoliths are borne in a rather compact mass upon the inter-laced tips of the sensory hairs (Plate 1, Fig. 3, *ot'lih*). They consist of irregular grains of sand mingled with other fine mineral particles and organic detritus. The largest measure from 8 to 12 μ in longest dimension. That the greater part of them are siliceous is shown by their insolubility in strong sulphuric acid, and by the fact that they scratch glass when crushed upon it. They are renewed after each moult, for the freshly formed sac is at first without them. New otoliths are pushed in by means of the chelæ through the aperture of the sac while its walls are yet so soft and flexible as to admit quite large grains of sand. By watching animals soon after moulting it can be observed that they stir up the sand at the bottom of the aquarium in which they are confined; as soon as some particles have come to rest upon the dorsal side of the antennule, one or both chelæ are raised, and by their tips the grains of sand are pushed back under the protecting lid of the opening into the otocyst. Otocysts from which most of the sand particles had been carefully removed by forcing a jet of water into the sac were found after a lapse of two days to contain otoliths derived from iron filings which had been strewn on the bottom of the aquarium. The otoliths are often entangled in the feathery plumes of the auditory hairs, and are in this case attached to them by an organic substance, which is probably secreted by unicellular glands situated beneath the floor of the sac. No multicellular glands, such as are found in the lobster and crayfish, could be detected beneath the otocyst of *Palæmonetes*. Very minute canals, which are probably the ducts of gland cells, were found running through the chitin wall and some distance into the tissues beneath; they were very clearly brought out, and their tubular condition proved beyond a doubt, in silver preparations, and in those made with lead formate; but unfortunately their connection with gland cells could not be demonstrated. The functions of the otolith and the part it plays in audition, or equilibration, will be discussed in the experimental portion of this paper.

2. *Innervation of the Otocyst.*

As already noted, the brain, or supra-oesophageal ganglion, is less than a quarter of a millimetre distant from the ear sac. The nerve supplying the hairs of the otocyst is thus comparatively short, and can be traced in a single section from the central to the sensory termination. Figures 4 and 12 (Plates 1, 3) show its general course after leaving the brain. Its sensory ganglion lies directly beneath the posterior end of the sac. The nuclei of the nerve cells of the ganglion are situated about 0.25 mm. back of the hairs which they innervate, grouped irregularly together; the peripheral fibres of the cells run somewhat parallel to one another, then spread out radially to the different hairs of the circle which they supply (Plate 3, Fig. 12, *fbr. p'ph.*).

There are three questionable points to be settled in regard to the innervation of the otocyst, and the same is true for the sensory bristles of decapod Crustacea in general.

a. Is each hair supplied by one nerve fibre and sensory cell, or by many?

b. How do the peripheral fibres terminate? Do they attach themselves to a sense cell, or to some part of the hair, or do they end free? If this latter be the condition, does the fibre terminate at the base of the hair, or at its very tip?

c. Where do the fibres end in the central nerve organ, and how?

For the determination of these questions, it is important to compare the conditions found in all kinds of sensory bristles. Because different types of hairs have been used in various Crustacea for the study of the nerve terminations, and this difference in kind of material employed by various investigators may account for the very diverse conclusions they have drawn.

All sensory bristles of decapod Crustacea can be divided into two general types:

(1) *Tactile bristles* (Plate 2, Fig. 8) have typically a long, straight, plumed, attenuate shaft, attached at the base by a thin spherical enlargement, which allows great freedom of movement.

Auditory hairs, so called, are merely modifications of these, for all gradations between the two exist. Tactile hairs are found on nearly all the appendages, and on some parts of the body.

(2) *Olfactory bristles* (Plate 4, Fig. 13, *set. olf.*, and Fig. 14) are short, cylindrical, or slightly tapering, and firmly attached as compared with tactile hairs, there being no marked basal enlargement. At the tip, the

chitin is either pierced by a pore, or ends in a thin permeable membrane, which allows substances in solution to enter the cavity of the hair. If found on the first or second antennæ, they are termed *olfactory* hairs; when on the oral appendages, *taste* or *gustatory* bristles, though their functions are probably the same.

a. Number of Nerve Elements to a Single Bristle. Until 1891 it was supposed that only a single ganglion cell and fibre-process supplied each hair. Then Vom Rath ('91, p. 207) asserted, that *beneath every sensory hair of crustaceans there is a large group of ganglion cells, each sending out a peripheral process, these converging and entering the base of the hair as a single large strand.* This opinion he again expressed in 1894 for all arthropods. He did not study the innervation of the otocyst, but apparently confined his attention to the olfactory type of hair, as his figures are all of unfringed bristles.

The number of elements supplying each hair of the otocyst can be determined by, first, counting the number of fibres in the auditory nerve, and the number of nerve cells connected with these fibres, and then, secondly, comparing the statistics thus obtained with the number of hairs in the otocyst. If there is but a single cell and fibre to a hair, these numbers should coincide, at least approximately. But if there are always numerous elements, as Vom Rath maintains, then the number of fibres and nerve cells should be many times that of the hairs. The number of fibres can be readily counted in a transverse section of the otocyst nerve stained intensely with iron hæmatoxylin and only slightly decolorized. The ganglion cells can be enumerated in serial sections cut in the plane of the long axes of the cells, so that their characteristic size and bipolar condition (seen in Plate 2, Fig. 6) will readily distinguish them from the hypodermal or matrix cells. From many such counts, the number of nerve elements was found to be approximately equal to that of the hairs. For example, in one otocyst there were 55 hairs, 53 fibres in the nerve supplying them, and 58 cells connected with these. The number of cells could not be determined with perfect accuracy, as some cells may have been halved in sectioning. Slight variations in the numbers, however, are not of great significance, as, in order to have even two nerve elements to a hair, the number of fibres or cells must be at least twice as large as that of the hairs. Moreover, the ganglion cells are always isolated, and each is surrounded by a separate sheath; their fibres are also separated from each other. Neither cells nor fibres occur in groups surrounded by a common sheath as Vom Rath ('92) describes them. *In the otocyst, then, there is but one nerve element to each hair.*

In the *tactile hairs* the same methods of procedure were followed; and further evidence was obtained from methylen-blue preparations. One of these is shown in Figure 11 (Plate 3). It will be observed at once from this figure that there is only one cell and one fibre to each hair. But in other preparations of the same appendage (Plate 4, Fig. 14) from two to ten cells are found grouped together irregularly, and sending all their processes to the same bristle. When this was the case, *it was always observed, that the hair so supplied was of the short, blunt, fringeless type*, and so possibly not a *tactile* but an *olfactory* hair.

So far, the evidence has been entirely against Vom Rath's statement; but if we examine the innervation of the *olfactory bristles*, entirely different conditions will be found to exist, and in complete accord with his conclusions.

On the inner flagellum of the first antenna of *Palæmonetes* numerous olfactory bristles are found, arranged in rows of four or five hairs each (Plate 4, Fig. 13). The nerve cells and fibres supplying these hairs stain beautifully with methylen blue. Only single elements at first appear, but if the stain is allowed to act for a longer period, nearly every cell and fibre will become impregnated. It can then be seen that a large number of elements supply each hair. The cells are packed so closely together as to make the counting of a group difficult, but many counts upon sections stained in hæmatoxylin make it certain that more than a hundred cells may compose a single group, and supply a single olfactory hair. The cells send off each a peripheral fibre. These fibres enter the base of an olfactory hair as a single large strand, 12 to 15 μ in diameter. In Figure 13 only a few of the elements are shown; the sheath, which surrounds both cells and fibres, marks the outline of the spindle-shaped group of cells, and shows the size of the fibre strand.

The *gustatory hairs* on the oral appendages are also each supplied with numerous nerve elements (Plate 4, Fig. 14). The number is not nearly so great as in the olfactory hairs, — averaging about 10 to a hair, — nor are they so regularly and compactly grouped. They differ markedly, however, from the conditions found in tactile and otocyst hairs.

The distinctly different conditions — as regards the number of nerve elements of the hairs — found in the olfactory and otocyst bristles, seem to explain the diverse conclusions of Bethe and Retzius on the one hand, and Vom Rath on the other. The two former observers worked on the tactile type of sensory bristles, while Vom Rath, as his figures show, evidently confined his attention to the other type. The conditions which

Vom Rath found in the olfactory type he too hastily attributed to all the sensory hairs of Crustacea.

b. Peripheral Terminations. Here again we find a difference of opinion. Heusen ('63, p. 368) asserted that the peripheral fibre was attached to a process (*lingula*) from the base of the hair shaft. Claus ('91), Vom Rath ('92, '94), and Bethe ('95) found fibres reaching to the very tip of the sensory bristles; while Retzius ('95, p. 17) found no evidence of nerve terminations beyond the enlargement at the base of the hair in *decapods*, though he observed in *Entomostraca* the same conditions as did the other three investigators.

I have obtained hundreds of preparations of nerve endings in the various sensory hairs of *Palæmonetes* with several of the best modern nerve methods, and all furnished the same evidence. The conditions found for otocyst hairs were in *every* case as illustrated in Figures 4 and 8 (Plates 1, 2). The ganglion cells, as already noted, lie at some distance (0.25 to 0.40 mm.) from the bases of the hairs which they supply. The reason for this becomes obvious, when the formation of the new hairs is considered. The developing hair tube extends below the base of the old hair a distance equal to at least one-third the length of the hair, and the ganglion cells necessarily lie below the lower or proximal end of the hair tube (Plate 3, Fig. 10, *ib. set.*). Hence they must be at least a third the length of the hair distant from its base, though they occupy a closer position directly after ecdysis than for some time before. The terminal fibres (Plate 2, Fig. 8, *fbr. n.*), which are as long as the distance of their cells from the hairs, enlarge slightly as they near their termination, and always end in the expanded base of the hair directly below the shaft proper. There are no signs of attachment to any part of the wall of the hair, nor of fine branching of the distal end of the fibre, such as Retzius ('90) describes. Figure 4 (Plate 1) shows diagrammatically one nerve element of the otocyst, the position of the ganglion cell, and the ending of its peripheral fibre in the base of the hair. In Figure 8 (Plate 2) only the termination of the fibre, highly magnified, is given.

The elements of the *tactile hairs* end in precisely the same manner as those of the otocyst. A number of these endings are shown in Figure 11 (Plate 3). In no case was a nerve ending demonstrated in the shaft of the hair. Thus, all the evidence of preparations goes to prove that in *both otocyst hairs and tactile hairs the nerve fibre, without branching, ends in the enlargement at the base of the hair, and never enters the shaft itself.*

In the *olfactory bristles* the cells are situated about 0.45 mm. posterior to the bases of the hairs, and their peripheral nerve fibres, stained by methylen blue, were traced *in almost every preparation, some distance into the shafts*, though in the *tactile* hairs of the same appendage no fibres could be followed further than the base. Figure 13 (Plate 4) shows the olfactory endings, some of them extending half the length of the hair shaft, but *none as far as the tip*; nor was such a condition ever found, although a great number of preparations were examined. The direct evidence of preparations shows, then, that *the peripheral nerve endings are different for the different types of hairs. The fibres terminate in the enlarged base of tactile bristles, while in olfactory hairs they end free in the shaft itself.*

This direct evidence is strengthened by other structural conditions.

(1) Owing to the rigidity of the hair shaft and its delicate basal attachment, a mechanical stimulus applied to a tactile hair would be apt to produce its strongest effect at the base. Therefore we should expect to find the nerve termination at this, the point of greatest stimulation. The innervation of the tactile hairs of vertebrates extends only to the base, yet the slightest touch of the hair tip stimulates the nerve ending.

Similarly, in the otocyst hairs the point of greatest stimulation must be at the base. The hair tips are so entangled with each other, and with the otoliths resting upon them, that a stimulus applied to one must affect them all. If this stimulus is caused by the shifting of the weight of the otoliths resulting from a change in the direction of the pull of gravity, it will affect the delicate, labile articular membrane at the base of the hairs far more vigorously than the part of the shaft attached to an otolith, or entangled with the tip of another hair which is so attached.

In the olfactory hair, on the other hand, the chemical stimulus finds access through the permeable tip, and, traversing the cavity of the shaft, comes at once into contact with the terminations of the nerve, which here, as we have seen, runs some distance toward the tip of the hair. This, then, is a condition of affairs which, in view of the function of the olfactory hairs, we should reasonably expect.

(2) The *conditions during hair formation* are very unfavorable to the assumption that the nerve fibres extend to the tips of the tactile and auditory hairs. In adult *Palæmonetes*, a month at least before ecdysis takes place, the matrix cells withdraw their processes to the basal portion of the hair, leaving the upper part of the shaft empty. As the

shrimp moults once in two or three months, this means that for nearly half the time the nerve fibre cannot extend further than the base of the hair. Yet the animals are apparently as sensitive to stimuli during this period as at any other. After the new hair is fully formed, and its tip projects into the base of the old hair, which has now lost all direct nerve connection, the animals still respond quickly to tactile stimulus; the impulse resulting from the stimulus is transmitted from the tip of the old hair to its base, thence to the shaft of the new hair, by which in turn it is transferred to the nerve fibre.

(3) If certain of the nerve fibres supplying the tactile hairs are stained with methylen blue just before ecdysis when the new hairs are fully formed but still deeply invaginated (Plate 3, Fig. 10, *tb. set.*), they may be traced some distance into the shaft of the *new* hair. Now, by removing with a fine needle the old test, *etc.*, the new hairs can be pulled out into their functional position. The nerve fibres, however, are not pulled out with the hair the whole distance, but remain nearly in their original relative positions, barely projecting into the bases of the hairs, a condition already pointed out in Figure 11 (Plate 3).

It is unfortunate that the investigators of these nerve endings have never taken into account the tissue changes — certainly of great importance — which occur in all Crustacea between moults.

At certain stages in their formation the delicate protoplasmic processes in the tips of the new hairs stain very sharply, and have a varicose appearance, similar to that of nerve fibres; as these project some distance into the old hairs, they might easily be mistaken for terminal nerve endings.

c. Central Terminations. By means of methylen-blue preparations the nerve fibres supplying the otocyst were traced continuously in their course from the sac to their central endings. Whole preparations of the antennules and brain could be used for this purpose, as the tissues were extremely transparent. On account of the proximity of brain and otocyst, the nerve supplying the latter is very short. It enters the anterior end of the brain lateral to the antennular nerve, the two joining as they pass within (Plate 3, Fig. 12). While the antennular nerve pursues a straight course, the other (Figs. 2, 4) descends from the sensory hairs in the floor of the otocyst, forms the sensory ganglion, and in continuing its course approaches somewhat the median plane and describes the form of an elongated letter S, the plane of which is dorso-ventral. Just before the two nerves unite to enter the brain, a third smaller

nerve is received by the otocyst nerve on its dorsal side (Plate 1, Fig. 2, *rm. l.*). This nerve is formed by an aggregation of fibres from the tactile bristles of this segment of the antennule, and runs almost straight toward the median plane till it joins the nerve of the otocyst. The fibres of the latter enter the anterior end of the brain ventral to the optic neuropil, and median to the globulus (Plates 1, 3, Figs. 4, 12); they extend backward to near the posterior end of the central organ in an almost horizontal plane, lateral to the fibres of the antennular nerve. They end in a region just anterior and median to the neuropils of the second antennæ, branching into delicate dendritic fibrillæ, which form a well-marked neuropilar mass (Fig. 12, *fbr'*).

Fibres supplying the tactile hairs of the basal segment of the antennule end in the same neuropil, while the main nerve to the antennule ends in a closely connected fibrillar mass just median to it. No nerve cells were found in the brain connected with the sensory fibres from the otocyst. Association elements, with large dendritic branches, put these neuropils into communication with the optic centres. One of these connecting fibres is shown in Figure 12 (*fbr. ass.*). Its cell, which supposedly exists, was not stained. According to Bethe's ('97, Taf. xxviii. *an.1*) experimental work on the brain of *Carcinus mænas* some of the otocyst fibres should end in the globuli. He could not demonstrate such fibres, however, in his preparations of the crab's brain, nor was I able to obtain conclusive evidence of such endings in the globuli of *Palæmonetes*.

d. Histology of the Nerve Elements. The nerve fibres of *Palæmonetes* are relatively large; those of the otocyst reach their greatest size immediately before they enter the neuropil substance of the brain. At that point in their course they are from 3 to 5 μ in diameter, not including the nerve sheath. In a transverse section of the nerve the separate fibres show distinctly, as they are held apart by connective tissue.

The *fibrillar* structure was made out definitely only in methylen-blue preparations which had been well differentiated in process of fixation. The gold-chloride method of Apáthy, though tried several times, did not give a successful reaction. Fibrillæ were made out distinctly in only one preparation, though some evidences of such structure appeared in many. Figure 15 (Plate 4) shows a portion of a peripheral fibre in which many fibrils are seen running longitudinally. No single fibril was traced any considerable distance, nor could any evidence of the fibrils be found in the ganglion cells. The fibrillæ are embedded in a

semi-fluid, homogeneous substance, which is the first to take up the methylen-blue stain. It has been called by Bethe ('98) the "perifibrillar substance." The accumulation of this fluid into drops gives the characteristic beaded appearance of methylen-blue preparations.

A distinct nucleated *myelin sheath* surrounds both the fibre and the peripheral ganglion cells of Palæmonetes. This sheath, which stains intensely black in Vom Rath's platino-osmic fixative, can be traced some distance beyond the peripheral ganglion cells toward the sensory hairs, and also centrally into the brain, where it ceases only when the fibres enter the neuropil substance. Figure 16 (Plate 4) shows a ganglion cell and its peripheral process surrounded by the sheath. Elongated, flattened nuclei occur at intervals along the walls of the sheath, curved around it and the enclosed fibre; certain of these sheath nuclei can be seen in Figure 4 (*nl. tu.*) between the ganglionic cells and the brain, though the myelin sheaths are not stained in this hæmatoxylin preparation. Quite frequently one of them may occur in close proximity to a ganglion cell. Thus are produced (Plate 4, Fig. 17) appearances which might be mistaken for a ganglion cell with two nuclei. Careful study, however, shows that one nucleus (*nl.*) lies within the cell, the other (*nl. tu.*) without, but abutting on the ganglion cell so closely as to sometimes change its form. In every instance of this kind one of the nuclei, owing to its irregular outline, its smaller size, and the curved form which it takes in adaptation to the surface of the cell, could be identified as belonging to the sheath rather than to the nerve cell.

The *peripheral ganglion cells* are much elongated and are of the typical bipolar form (Plate 4, Fig. 18). They measure from 10 to 14μ in diameter; their nuclei are relatively large, measuring from 7 to 9μ in diameter, and are usually ovate in outline, their length in some cases being twice as great as their diameter. One large spherical nucleolus is usually present in the chromatic network, though sometimes two or more are found. No definite structure can be recognized in the cytoplasm of the cell, nor any traces of fibrillæ; this, however, is not strange, as the cell usually stains so intensely that it would not be reasonable to expect to make out its finer structure. In methylen-blue preparations a narrow zone about the nucleus stains only faintly, the coloration becoming more intense as the periphery of the cell is approached; so here, as Bethe also found in the nerve cells of Carcinas, the chromatin granules are more numerous at the periphery of the cell cytoplasm, and nearly wanting around the nucleus.

3. *Development of the Otocyst (in Homarus americanus Milne-Edwards).*

In order that the development of the otocyst in the lobster may be more readily understood, it may be best to compare briefly its adult condition with that of *Palæmonetes*.

It was dissected and described by Farre ('43), and again by Hensen ('63). The sac is drawn out posteriorly into a dorso-ventrally flattened projection, the "cochlea" of Hensen. The external aperture is extremely small, guarded by bristles, and located at the median, dorsal, and anterior end of the sac, the dorsal wall of which, like the dorsal wall of the antennule, is very thin, forming the so-called tympanic membrane. On the floor, which is nearly horizontal, there is a semi-circular ridge (Plate 5, Figs. 24, 26), which forms the sensory cushion. From this arise the otolith hairs, which have straight shafts, and number from 500 to 600. The four rows of these are so arranged as to form a semi-circle, the open side of which (at the right in Plate 5, Fig. 26), is anterior instead of posterior as in *Palæmonetes*. At the anterior end of the curve there is an irregular group of smaller hairs, with bent shafts. On the median wall of the sac, near its posterior end, there is an irregular double row of long thread-like hairs, with shafts heavily fringed (Fig. 26, *set. m.*). The otoliths are numerous, and rest on the area surrounded by the rows of sensory hairs, and also on the hairs themselves; the thread-like hairs are free, and float out into the lumen of the sac.

Not much has been written on the development of the otocyst in decapods. Reichenbach ('86), in his work on the embryology of the crayfish, figures the invagination of the "auditory sac" at an early stage in the egg. The crayfish, however, as it develops into the adult form without passing through the larval stages characteristic of most other decapods, is not a typical example. Herrick ('95, p. 194) alludes to the appearance of the otocyst cavity in the third larval stage of *Homarus*, and he shows its position at this stage in connection with the development of the first antenna. In the fourth stage it is a shallow depression containing a few otoliths and in the fifth larva its aperture begins to close.

I shall describe its condition in the first four larval stages.

a. *First Larval Stage.*

(Schizopod larva, without abdominal appendages.)

Sections of lobster eggs in different stages up to time of hatching showed no evidence of the otocyst in the antennule, and it became

apparent that its development took place wholly in the free-swimming stages. A transverse section through the antennule of a newly hatched larva (Plate 4, Fig. 19) shows no sign of invagination in the region where the sac is to appear. But certain elongated nuclei, evidently those of modified hypodermal cells, are found grouped, two or three layers deep, beneath the dorso-lateral wall of the appendage (Fig. 19, *cl. ma.*). These elongated nuclei, viewed from the dorsal surface of the appendage, are seen to be roughly arranged in a semi-circle, like the rows of otocyst hairs in Figure 26 (Plate 5), and when traced through later stages, the position they occupy is found to be directly beneath the ridge where the sensory hairs later appear (Plate 5, Fig. 24, *set. ot.*). They are evidently, therefore, the nuclei of the matrix cells which build up by secretion the chitinous walls of the sensory hairs. These cells, like those which take part in hair formation after ecdysis, originate from the chitinogenous hypodermal cells by simply becoming elongated and sinking beneath them. A similar arrangement of matrix cells was found in the developing otocyst of *Mysis* by Bethe ('95^a). Numerous spherical nuclei, which stain in a manner characteristic of nerve cells, are present just below the matrix cells (Fig. 19, *n'bl.*). If traced back to the ganglionic masses of the brain, they are found to be continuous with the nerve cells of the latter, and probably originate from them.

b. Second Larval Stage.

(Second to fifth pair of abdominal appendages present.)

In this larva the first evidence of invagination is seen on the dorsal side at the base of the antennule (Plate 4, Fig. 20). The nuclei of the matrix cells are now larger, and very conspicuous at the lateral side of the transverse section, the region where the rows of hairs will later appear. Figure 22 (Plate 4) shows the anterior and posterior limits of the invagination and the fundament of the *sensory ridge*, marked by a fold in the hypodermis and chitin at *cl. ma.* The matrix cells just posterior to this fold, whose processes are directed toward it, are those which are to form the transverse portion of the hair rows. As in the first stage, nuclei of nerve cells lie immediately beneath the matrix cells, but the cytoplasm about them shows as yet no definite boundaries or outlines, nor are there any signs of nerve fibres connected with them.

c. Third Larval Stage.

(Chelæ relatively larger, uropods present.)

In this stage (Plates 4, 5, Figs. 21, 23) invagination has proceeded

still further. There is a deep lateral, as well as a posterior, fold in the chitin; but the sac, if it can now be called such, is very shallow, wide-mouthed, and without sensory hairs or otoliths. From the group of matrix cells, however, the tips of embryonic sensory hairs may be made out, projecting dorsally, but covered by the chitinous floor of the sac (Plate 5, Fig. 27). Only after the wall of the sac has been shed at the next moult will they become functional organs.

d. Fourth Larval Stage.

(Form like that of adult; thoracic exopods rudimentary.)

The sac has now greatly increased in size, and nearly fills the cavity of the appendage (Figs. 24, 25). Its opening has become smaller, and is protected by numerous fringed bristles, which project from its sides (Fig. 25, *tct.*). About 200 sensory hairs are present borne on a prominent sensory ridge (Fig. 24, *set. ot.*) and arranged in three regular rows, one row less than in the adult stage (Fig. 26). The whole band bears some resemblance to a sickle. Beginning at the median side of the sac floor, the rows curving only slightly run laterally, then with a stronger bend turn forward. At the anterior end of the sac regular arrangement ceases, the hairs being grouped promiscuously. Besides these large hairs on the sensory ridge, which measure $120\ \mu$ to $150\ \mu$ in length and from $4\ \mu$ to $6\ \mu$ in diameter, there is, as in adults, an irregular row of more attenuate hairs arranged longitudinally along the posterior part of the median wall (*set. m.*, Fig. 26). They number about thirty, are on the average $140\ \mu$ in length, and have a diameter of only $2\ \mu$ to $3\ \mu$ at the base of the shaft.

Many otoliths, consisting of fine particles of sand, rest on the hairs of the sensory ridge, as in the adult condition, but do not come into contact with the attenuate bristles of the median side-wall, which project free into the liquid contents of the otocyst. The sensory ridge is much more prominent at this stage than in the adult. This, and the size of the aperture, are the chief differences between the two, and are well shown in Figure 25. The opening gradually becomes smaller in the fifth, sixth, and seventh stages, until in the full-grown animal it is almost obliterated. A fourth row of hairs, not yet developed, is formed posterior to the others at some stage later than the seventh moult, this being the oldest stage that I have studied. Except for the gradual closure of the aperture, the larvæ of the fifth, sixth, and seventh stages show the same conditions in the otocyst as the stage under consideration.

In Figure 24 (Plate 5) ganglion cells (*cl. gn.*) are seen beneath the

sensory ridge. The origin of these could not with certainty be traced out in the material at command, though from the conditions found in the first stage, it is probable that they are derived from the neuroblast cells of the brain. The only evidence in favor of this view is the proximity of the brain, and the fact that at an early stage nerve cells which were continuous with the ganglionic masses of the brain were present beneath the matrix cells of the otocyst. Figure 26 shows, somewhat diagrammatically, the general innervation of the otocyst hairs of the fourth larval stage, as brought out by methylen blue. The condition is essentially that of the adult. There is but one nerve element to each hair, and the endings are in the enlarged bases. No myelin sheath is developed in either the larva or adult lobster. Central terminations of the otocyst fibres were not traced out, nor was their finer histology investigated.

The most striking point to be noted in the development of the otocyst of the lobster is the abrupt change which takes place after the third moult. The shallow, functionless depression of the third stage is converted at once into the active, well-differentiated organ of the fourth larva. This sudden leap in the development of the otocyst is correlated with an abrupt metamorphosis of the larva's general form and method of locomotion. As this correlation may have an important physiological significance, it will be discussed in detail in the theoretical portion of this paper.

II. CRANGON VULGARIS SAY.

1. *Structure of the Otocyst.*

a. Sac. The otocyst has been described only briefly by Hensen ('63). He figures the sac dissected out, and gives two sketches of the sensory hairs, and the prominence upon which they are borne.

The sac, as seen in a section passing through its middle and transverse to the long axis of the antennule, has the form of a half-circle. In a cross-section more posterior its outline is made irregular by the projection of the *sensory ridge* or cushion from its *lateral wall* (Plate 6, Fig. 28). This is an entirely different condition from that found in *Palaemonetes*, where the sensory cushion is basal. More irregular still is its form in frontal section, as shown at *crs. sns.* in Figure 29 (Plate 6). The dimensions of the sac in individuals of medium size (25 mm. long) are :

length 0.44 to 0.55 mm.

width 0.28 " 0.38 " (anterior to sensory ridge)

depth 0.20 " 0.22 "

It is thus relatively wider, and more shallow than that of *Palæmonetes*. The wall is of thin chitin continuous at the large oval aperture (Plate 7, Fig. 30) with that of the dorsal side of the antennule. The aperture is as wide and nearly as long as the sac itself; instead of a fold of chitin it has for protection a row of large fringed bristles. These are ranged close together along the posterior edge of the opening and extend their long parallel shafts beyond its anterior margin. A fine-meshed grating is thus formed, through which even microscopic organisms could not pass without displacement of the bristles.

b. The sensory cushion (Plate 6, Fig. 29, *crs. sns.*), as already noted, projects from the posterior portion of the lateral wall of the sac. Its direction is not transverse to the long axis of the sac, but it points obliquely forward and mediad. It is a *ridge* rather than a cushion, for the hairs are arranged in a short, nearly straight single row, instead of in several rows having the form of a sickle. This row of hairs, which defines the limits of the sensory region, starting at the dorsal end of the ridge, takes a course along its convex surface downward and backward, and ends where the ridge disappears, just before the floor of the sac is reached. A portion of a row of hairs is shown in the right otocyst, Figure 29, *set. ot.* (Plate 6), where the hairs anterior in position are really above or dorsal to those posterior to them. The ridge-like projection of the sensory prominence is best seen in a parasagittal section (Plate 7, Fig. 30, *set. ot.*), a hair being there shown at the apex of the ridge.

The matrix cells are essentially the same as in the hairs of *Palæmonetes*. They occupy the region just beneath the bristles, into which their processes extend. The space in the sensory prominence below and lateral to the matrix cells is occupied by the sensory ganglion cells, the fibres from which penetrate between the formative cells and reach the bases of the hairs (Fig. 29, *cl. gn.*).

c. Structure of hairs. Arranged on the sensory ridge in the manner above described, the hairs of the otocyst are 26 in number, as shown by the average of a large number of individuals. They are largest at the upper anterior end of the row, where they measure 180μ in length and about 9μ in diameter at the base of the shaft. Proceeding down the line they are successively smaller, the last of the series being only 100μ in length and 6μ in diameter. There is a conspicuous spherical enlargement at the base of the hair shaft (Plate 7, Fig. 31, *mb. sph.*), as in the otocyst hairs of *Palæmonetes*. The shaft itself for about a third of its length projects straight out horizontally into the lumen of the sac. Then it bends down ventrally nearly at right angles, though the amount

of curvature is different for different hairs. The larger, being in a more elevated position, usually bend at a sharper angle than those near the floor of the sac. All are heavily plumed; the pinnules are long and coarse (Plate 7, Fig. 31, *pinn.*) and often have otoliths firmly attached to them by a substance probably of glandular origin. Hensen ('63) describes the otolith hairs of Crangon, as follows: "Es steht nämlich auf die schon erwähnten Vorbuchtung eine einzige Reihe von 7 oder 8 Haaren; diese Haare reichen bis zur Kugel in die Steine hinein, ihre Zahl erscheint viel zu gering für deren Masse. . . . Sie sind 0.075 mm. lang, 0.0075 mm. breit und gerade aufgerichtet."

This description of these hairs is completely at variance with the conditions I have found in the American Crangon. In order to determine, therefore, whether this was a true specific difference, or due to an error on Hensen's part, a number of the European specimens, procured by Dr. Mark from Professor Herdman in Liverpool, were examined. After dissecting out the otocysts of 12 specimens, I was entirely satisfied that Hensen's description was incorrect. The hairs are precisely the same in size, form, and number as in the American variety. They have their shafts distinctly bent near the tip at angles varying from 25° to 90°; of the individuals examined none possessed less than twenty-four hairs in the sac, the average being twenty-six.

That Hensen should have made such a mistake is not strange. He himself says: "their number appears much too small for the mass [of the otoliths]." The tips of the hairs are concealed by the otoliths, and only the first third of the row would be visible from above.

d. The formation of hairs after ecdysis is identical with that of Palæmonetes.

e. The otoliths are numerous, larger than in Palæmonetes, and found mostly in the posterior part of the sac, in contact with, or even attached to, the fringed tips of the hairs. Mainly siliceous, they are taken in after each moult, being readily pushed into the large opening of the otocyst. They can be almost completely washed out by a fine jet of water introduced artificially, and if the animal so treated is then placed in an aquarium containing iron filings, or other substitute, this material will soon be used to replace the otoliths of sand.

2. Innervation of the Otocyst.

As in Palæmonetes, the brain is very close to the otocyst, and the nerve supplying the sac is therefore short. Its general course is shown at *n. ot.* in Figure 29 (Plate 6).

Leaving the anterior end of the brain with a bend away from the median plane, it gives off in front of the globulus a small lateral branch (*rm. l.*), which supplies the tactile bristles of the antennule. The main nerve, after passing between the globulus and the posterior end of the sac, runs forward only a short distance to the sensory prominence on the lateral side of which its ganglion lies. The peripheral fibres can be traced forward and slightly mediad from the ganglion to the bases of the otocyst hairs. The whole course of the nerve is approximately in a frontal plane, though its peripheral ending is slightly more ventral than its point of departure from the central organ. In Figure 28 (Plate 6) the transverse section of the antennular nerve (*n. at. I*) is seen to be median to the sac, while the ganglion cells of the otocyst nerve (*cl. gn.*) are lateral to it.

a. Number of Nerve Elements to a Single Bristle. There is in Crangon but one ganglion cell and fibre to each otocyst hair. The cells and fibres were counted as in Palæmonetes, and the numbers thus obtained were found to agree approximately with the number of the hairs.

Methylen-blue preparations of the olfactory nerve elements were obtained, and the conditions there brought out agreed essentially with those found in the same type of hair in Palæmonetes, large groups of nerve cells being present beneath each olfactory bristle.

b. Peripheral Terminations. Nerve fibres to otocyst hairs were never traced beyond the enlarged base of the bristle, where they end free without branching. A typical nerve element of the otocyst is given diagrammatically in Figure 29; it shows the peripheral ending of the fibre at the base of *set. ot.*

In the olfactory hairs, on the other hand, the nerve fibres in most cases could be traced up into the shaft of the hair, though never through its whole length. Thus in Crangon, as in Palæmonetes, there is a distinct difference in the innervation of the two types of bristles, both as to the number of elements, and in the manner in which the fibres end.

c. Central Terminations. Centrally the otocyst nerve ends in a position (Fig. 29) corresponding to that of the central terminations in Palæmonetes, but the fine fibrillar branching, which was brought out distinctly by methylen blue in that form, could not be impregnated in Crangon.

d. Histology of the Nerve Elements. So far as worked out, this was similar to that already described in Palæmonetes. A myelin sheath is present in Crangon as well as Palæmonetes, though it was not observed in any other decapods.

3. *Development of the Otocyst.*

This was not studied in Crangon.

III. CAMBARUS AFFINIS (SAY) GIRARD.

The otocyst of the crayfish has been figured by only Farre ('43) and Huxley ('80). The description of the former investigator was excellent for the time at which it was made. Huxley alludes to the otocyst in his work on the crayfish, and gives one figure showing the sensory region dissected out. Hensen ('63) describes the hairs of the otocyst in *Astacus fluviatilis*, but does not touch upon its other structures.

1. *Structure of the Otocyst.*

a. Sac. The otocyst of *Cambarus* (Plate 8, Figs. 37, 38), except for its smaller size, resembles that of the lobster very closely. The aperture, exceedingly small in the lobster, is here quite large, though, on account of the dense *chevaux de frise* of fringed bristles, it seems smaller than it really is. These bristles, projecting from around its margin, effectually cover and conceal the opening. It occupies the middle of the dorsal side of the antennule; its anterior margin corresponds to the anterior wall of the otocyst, and it extends back from this point nearly one-half the length of the sac. Its width is about one-third that of the otocyst (Fig. 37).

The cyst does not by any means fill the cavity of the antennule. It is rounded off in front, but sharply pointed at its posterior end, where it is very shallow (Fig. 38). Its walls are of uncalcified chitin and continuous with the very thick calcified shell of the antennule (Figs. 37, 38). Its dimensions in average-sized animals are:

Length from 1.75 mm. to 2.25 mm.

Width " 1.52 " " 2.10 "

Depth " 0.85 " " 1.05 "

b. Sensory Cushion. The sensory ridge, or cushion, in the base of the otocyst is not prominent, as that part of the sac floor upon which the sensory hairs are borne is but slightly elevated above the rest (Fig. 38, *set. ot.*), and, contrary to the conditions found in the two forms already described, the sensory surface is nearly horizontal, instead of being vertical or oblique. The arrangement of the hairs is shown in Figure 40 (Plate 8). Three sets can be distinguished, corresponding to the divisions of the otic nerve,—a median, a lateral, and a transverse or posterior. The first and third are nearly straight, the second sickle-

shaped. The "median" set consists of a single nearly straight row, running from the posterior angle of the sac obliquely forward and mediad, back of which there are two or three shorter, irregular rows of scattered hairs. The lateral set consists of two concentric rows, which have the form of a crescent or the blade of a sickle, the handle of which is represented roughly by the nerve trunk connecting the bristles with the brain. The hairs of the outer row are much larger than those of the inner series. At the tip of the sickle blade the area covered by the bristles expands, and the hairs are arranged in 4 or 5 irregular rows. Behind the proximal end of this sickle-shaped double row of bristles is a short row of very large hairs, the posterior set (Fig. 40, *set. p.*), usually nine in number, which extends transversely across the posterior portion of the sac immediately in front of its pointed base. Matrix cells are found in the region directly beneath the hairs, as in the other forms described (Plate 8, Fig. 37), and the nerve cells with their peripheral fibres lie below the chitin, either just within (lateral set), or slightly posterior to (median and transverse sets) the rows of hairs (Plate 8, Fig. 40). By looking down upon the floor of the sac one can make out numerous small pores (represented in Figure 40 by minute circles), which penetrate the chitinous wall in that portion of the floor which is inclosed by the sensory bristles, especially in its lateral part. In transverse sections some of these pores are cut through, and it then appears that they connect with the ducts of multicellular glands which are located in the tissues beneath. One of these glands with its duct and pore is shown in Figure 39. It is apparently similar to the tegumental glands found in different parts of the lobster and figured by Herrick ('95, Cut 5, p. 77). In *Cambarus* these glands evidently supply the secretion which attaches the otoliths to the pinnules of the otocyst hairs.

c. Structure of Hairs. This has been described in some detail by Hensen ('63), to whose descriptions I have not much to add. The hairs are very similar in structure to those of the lobster. Their number varies greatly in different individuals, but is usually over 200. The straight, or only slightly curved, shaft is heavily fringed, and borne on the customary spherical base. Their dimensions are:

Length, from $65\ \mu$ to $175\ \mu$.

Diameter, " $15\ \mu$ " $18\ \mu$.

A transverse section of the shaft near its base has the peculiar shape shown in Figure 35 (Plate 7). This modification of the form of its wall, found also in the otocyst hairs of the lobster, doubtless renders the shaft more rigid than if it were a simple hollow cylinder.

The shaft, as already noted, is nearly straight, but it is attached to the floor of the sac in such a way as to make a very small angle with its surface, being, in fact, nearly parallel to it. Thus in *Cambarus* the bending has taken place at the base, not, as in *Palæmonetes* and *Crangon*, in the shaft itself. In these two forms the tendency of the shaft to bend must be aided, if not caused, by the weight of the otoliths attached to the slender tips of the hairs. In the lobster and crayfish the modified form of the shaft makes it too rigid to thus give way, and the bending, if any, must take place at the thin, membranous basal sphere.

d. *Formation of Hairs.* (Not studied in *Cambarus*.)

e. *Otoliths.* These are composed of large grains of sand distributed mostly within the circle of hairs, and supported in part by them. As the sac has a large opening, they are readily taken in through it after each ecdysis.

2. *Innervation of the Otocyst.*

As the crayfish was well adapted for work with methylen blue, a large number of preparations of the sensory nerve elements were made, not only of the hairs of the otocyst, but also of the other sensory bristles. The nerve supplying the otocyst issues from the ventral surface, instead of the anterior end, of the brain, and at once passes forward with a slight lateral curvature to the pointed posterior end of the sac, beneath which its fibres spread out to the different hairs. It divides roughly into two strands, one of which passes obliquely forward and mediad to supply the median set of bristles (Plate 8, Fig. 40), while the other follows the course of the lateral sickle-shaped set, lying on the concave side of the two rows, to which it gives off fibres along its whole course. Before this division of the nerve takes place, a few large fibres run out from it on the lateral side (Fig. 40) to supply the short transverse row of large bristles (Plate 7, Fig. 33).

The sensory nerve cells lie immediately beneath the hypodermis, and their peripheral fibres run in a plane parallel with the floor of the sac. In the case of the transverse row of large hairs, the nerve cells are situated about $450\ \mu$ posterior to the bases of the shafts, their peripheral fibres being therefore nearly half a millimetre in length. This is accounted for by the position of the new hair tube during the period of its formation between moults, when it extends back from the base of the functional shaft $350\ \mu$; the distance from base of hair to ganglion cell must consequently be somewhat greater than this.

a. Number of Nerve Elements to a Single Bristle. The number of cells and fibres for the whole sac could not be determined with exactness, as other sensory elements, supplying tactile hairs, are mingled with those of the otocyst. But in the short transverse row of large hairs, the cells and fibres are sufficiently isolated to allow of their being counted in serial sections. There are but nine hairs in that row, and if the nerve elements supplying them were twice as numerous, it would be at once apparent. The cells always occur singly, and their fibres run separately and parallel with one another to the bases of their respective hairs (Plate 7, Fig. 33). The number of each was counted many times, and it is certain that *the number of ganglion cells and peripheral fibres exactly equals the number of hairs*. Whole preparations of these nerve elements stained with methylen blue gave regularly nine ganglion cells and fibres supplying the nine sensory hairs. In these few otocyst hairs, at least, there is, then, but a single nerve element supplying each.

In the *tactile hairs* of the scaphognathite of the second maxilla, many methylen-blue impregnations gave conditions like that shown in Figure 34 (Plate 7), only one sensory nerve element being stained. In the short spike-shaped bristles found on this same appendage, from three to five ganglion cells (Plate 7, Fig. 32, *cl. gn.*) were usually found supplying each bristle.

In the *olfactory bristles* of the antennule, the conditions were the same as those already described and figured for *Palæmonetes*, though fewer elements compose each spindle-shaped group of cells.

b. Peripheral Terminations. No branching of peripheral nerve fibres was observed in any sensory elements, though many were traced the whole length of an appendage. In *Cambarus* the fibres end always at the base in the otocyst hairs (Plate 7, Fig. 33). There is often a marked increase in the diameter of the fibre near its termination, caused either by the staining of its sheath at this point, or by a partial separation of the component fibrillæ. *Tactile hairs* show similar conditions in their nerve endings (Plate 7, Fig. 34).

The fibre strands of the *olfactory bristles* were, on the contrary, traced into the shaft some distance, where they apparently end free. Thus in the crayfish, we have a distinct difference in the innervation of the two types of sensory hairs, which serves to confirm the statements made concerning the conditions in *Palæmonetes* and *Crangon*.

c. Central Terminations. The otocyst nerve in *Cambarus* is large enough to be dissected out and traced to the ventral side of the brain, which it enters lateral to the larger antennular nerve. Its point of en-

trance is a little to one side of the median plane of the brain, opposite the posterior end of the globulus (Plate 9, Fig. 41). Its fibres run backward and dorsad, just lateral to those of the antennular nerve, and end in a neuropil directly anterior and median to that of the second antenna (Fig. 41, *n. ot.*). The individual fibres end by branching into fine fibrillations, which could be traced only a short distance through the diffusely stained mass of fibrillar tissue about them.

d. Histology of the Nerve Elements. The sensory nerve fibres of *Cambarus* are relatively smaller than those of *Palæmonetes*. Immediately after leaving the ganglion cell each measures about 3μ in diameter, but becomes smaller as it runs distally, until near the point of ending, where it again enlarges to its original size. In well differentiated methylen-blue stains, fibrillar structure is clearly brought out. Longitudinal sections, and whole preparations of continuous fibres, show fibrillations similar to those figured for *Palæmonetes*.

The sensory nerve cells are relatively large; they measure from 15 to 18μ in diameter, and being bipolar are spindle-like in form. Their nuclei are spherical and from 10μ to 12μ in diameter. The cytoplasm of the cell never shows any evidence of fibrillations, but in methylen-blue impregnations there is a faintly staining zone directly about the nucleus; the remainder of the cytoplasm takes on a deep blue color. This difference in staining qualities may be due to the unequal distribution of chromatic substance in the cytoplasm.

The myelin sheath, so characteristic for the nerve fibres of *Palæmonetes* and *Crangon*, is not found in the nerve elements of the crayfish.

3. *The development of the otocyst* was not studied in *Cambarus*. According to Reichenbach ('86) it is completely formed before the young animal leaves the egg.

IV. CARCINUS MÆNAS LEACH. (*Green crab.*)

We now come to the second type of otocyst, which is found in all brachyuran Crustacea; it is closed, and without otoliths. Mistaken by Bate ('58) for an olfactory organ, and figured by him in the larval stages of the crab, it has been described carefully in *Carcinus mænas* by Hensen ('63) alone. His account, although fairly accurate, is influenced by his seeing a fancied resemblance between the otocyst and the vertebrate ear; the figures he gives of different parts of the sac dissected out leave one somewhat in the dark as to the relative positions of the structures described.

1. *Structure of the Otocyst.*

a. Sac. The basal segment of the antennule in *Carcinus* is relatively large, and elongated laterally to such an extent that its width is nearly twice its length (Plate 9, Fig. 46). Along its dorsal wall there extends transversely a distinct line dividing the chitin of the anterior part of the segment (*lab. a.*) from that of the posterior. This line of division, which reaches from the lateral margin of the segment three-fourths of the way across its dorsal wall, is rendered more prominent from the fact that the chitin posterior to it (*lab. p.*) is much lighter in color than that in front.

If the antennule of a crab is examined directly after ecdysis, when the chitin is still very thin, soft, and uncalcified, this lighter colored area (Fig. 46, *lab. p.*) is found to be a fold, projecting forward over the anterior part; and if its edge is lifted with a needle or fine pair of forceps, a transverse aperture is disclosed leading down to the lumen of the sac. This aperture extends from line 45 (Fig. 46) laterally down through the side wall of the antennule. There is, then, in fact, a free passage into the otocyst directly after moulting, a condition necessitated by the casting off of the old sac. But almost immediately after ecdysis, the opening is closed and its edges fuse together, probably owing to the simultaneous secretion of chitin by the hypodermis of the two surfaces which bound the orifice and are in direct contact. Figure 44 (Plate 9) shows at *lab. p.* the two surfaces which fuse.

The form of the sac is very irregular, so much so that Hensen despaired of describing it. Its walls, like those of the forms already studied, are continuous dorsally with the calcified chitin of the antennule (Figs. 42-48, Plate 9). The sac is thus suspended from the dorsal wall of the appendage. Although composed largely of thin chitin, one portion of its wall is much thickened and calcified (*mal.*, Figs. 43-48, Plate 9). On account of its irregular outline measurements can be of only small value. The average of a number of measurements taken of the otocyst in specimens approximating 30 mm. in length, gave the following results:—

Greatest length, 1.11 mm.

“ width, 1.96 “

“ depth, 1.05 “

The seemingly contorted shape of the sac is caused by three protuberances or invaginations of its walls, which project into the lumen (Fig. 4, and Plate 10, Fig. 55). Two only of these prominences are sensory and bear bristles (Fig. 4, *set. ta.* and *set. fl.*). The third and largest of

the three (*mal.*), which projects from the lateral and posterior wall of the cyst, is without sensory organs of any kind. Its wall is irregularly curved and pitted (Plate 9, Fig. 47 *mal.*), while portions of it are even calcified. At one point its walls are constricted to form a neck, which bears a large hammer-like head (Fig. 47). This is the "Hammer" of Hensen, compared by him to the malleus of the vertebrate middle ear. Figures 43, 48, and A show the relative position of this hammer to the

FIGURE A.

Model of the lumen of the left otocyst of *Carcinus*, dorsal view, the upper wall of the sac removed. The cavity of the sac was modelled in wax from serial sections under a magnification of 50 diameters, and a plaster cast of the model photographed natural size. In making the cut this was reduced to a magnification of 33 diameters. *a.*, anterior; *m.*, median; *set. l'*, group hairs; *set. fil.*, thread hairs; *set. ta.*, hook hairs.

rest of the sac. It serves merely for the attachment of the short, thick, powerful muscles of the antennule which keep the latter in almost constant motion, and has probably nothing whatever to do with the sensory functions of the otocyst.

b. Sensory Cushions. Of the three projections noted, the remaining two are sensory and bear sensory hairs (Plate 10, Fig. 55, *set. ta.*, *set. fil.*). The smaller of these (*set. ta.*), located on the median portion

of the posterior wall of the sac, bears a number of hairs with hooked shafts. The surface bearing these lies in a nearly vertical plane. From its position and the shape of its hairs this prominence is comparable to the sensory cushions upon the surfaces of which the otoliths are lodged in *Palæmonetes*, *Crangon*, and the crayfish. Irregularly disposed matrix cells are situated in clusters immediately beneath the hooked hairs (Plate 10, Fig. 50), and deeper in the tissues are the ganglion cells of the nerve fibres which supply the bristles (Fig. 50, *cl. gn.*). In the larval stages of the crab this sensory cushion is relatively much larger. It extends through half the length of the sac, and its hairs are in contact with the otoliths which the sac then contains. Pores of tegumental glands penetrate the chitin of this prominence, as they do that of the sensory cushions in the crayfish and lobster, although found in no other part of the sac. These glands secrete a substance which, in the larval crab, attaches the otoliths to the tips of the hairs. Their presence in the adult crab is evidence in favor of the homology of this cushion with that described for otocysts containing otoliths.

The other sensory cushion is much larger, and is produced by a partial invagination of a portion of the median and anterior walls of the sac, which forms an oval prominence (Fig. A; Plate 9, Fig. 48; Plate 10, Fig. 55, *set. fil.*). It is nearly 0.5 mm. in diameter, and its surface, making an angle of about 45 degrees with both the transverse and sagittal planes of the animal, inclines backward, inward and downward (Plate 9, Fig. 45). Its ventral portion is shown in transverse section in Figs. 47-48. The chitin of this cushion is very thin; upon it is a row of long delicate hairs, called by Hensen ('63) "Fadenhaare," or thread-hairs. This row runs down somewhat obliquely from the upper side of the prominence to its ventral margin near the floor of the sac, its dorsal end being the more anterior of the two (Fig. A, *set. fil.*).

This sensory cushion is also found in the sac of the larva, and the bristles it then bears are similar to those found projecting free into the lumen of the lobster otocyst from its median wall (Plate 5, Fig. 26, *set. m.*). The prominence we are now describing in *Carcinus* is probably therefore simply a further differentiation of the slight projection noted in the sac of the lobster.

Matrix cells send delicate processes into the hairs, as in those of preceding species; the ganglion cells are situated directly beneath the hypodermis, but some distance posterior to the bases of the hairs (Plate 10, Fig. 53, *cl. gn.*).

No gland pores are present, nor are they needed, as the thread

hairs are never in contact with the otoliths, even in the larval stages.

A third region, on which sensory hairs are located, is found at the extreme lateral side of the sac, beneath the fused lips of its opening (Fig. 4; Plate 9, Fig. 42, *set.*'). There is only a slight prominence, the surface bearing the hairs being nearly flat. The hairs are arranged in irregular fashion, somewhat like the groups of otocyst bristles situated near the aperture of the sac in the crayfish and lobster. Numerous groups of matrix cells lie directly below these hairs, but no nervous structures could be distinguished in their vicinity.

The great hammer-like prominence, which serves for the attachment of the antenuular muscles, separates the sac roughly into an upper, anterior chamber and a lower, posterior one. The first of these compartments is again partially separated into two by the anterior sensory prominence, which nearly meets the "hammer." These three chambers, into each of which sensory hairs project, were likened by Hensen to the semi-circular canals of the vertebrate ear, and the sensory regions to the *cristæ acusticæ*. As the compartments are in free communication, are not at all canal-like in form, and are arranged in no definite positions relative to each other which might be of functional importance, there seems to be no more logical reason for making such a comparison than for comparing the hammer-like projection of the otocyst to the malleus. The apparent division of the otocyst into three compartments is not a modification for the purpose of increasing its usefulness as a sense organ, but evidently a condition brought about mechanically by the differentiation of the "hammer" along lines which would make it better adapted for the attachment of muscles.

c. Structure of Hairs. The hairs, as already indicated in describing the sensory regions, are of three kinds. Hensen's account of them is fairly good. He divides them into the following classes: (1) hook hairs (Hakenhaare), (2) thread hairs (Fadenhaare), and (3) grouped hairs (Gruppenhaare).

(1) *The hook hairs* are found on the posterior vertical cushion (Fig. 4 and Plate 10, Figs. 50, 55, *set. ta.*) arranged in a very irregular curved row. They vary from 25 to 31 in number, and are relatively very small, averaging 49μ in length and 4μ in diameter. Their shafts are hooked, often bent nearly double, and are sparsely fringed near the tip, if at all. The base is enlarged, as is usual in otocyst hairs, but not so markedly as in the forms already studied. Instead of being attached to a large spherical membrane, the base of the shaft is set

into a cup-shaped depression and so labilely fastened to the chitin of the sac wall (Plate 10, Fig. 51) that the hair can sway freely in any direction, as if it were attached by a ball-and-socket joint. This cup-like depression is characteristic of all the otocyst hairs of Brachyura.

The hook hairs are present in the otocyst of the Megalops larva of Carcinus, and are there relatively much larger; they extend over a large portion of the posterior end and floor of the sac, the curved row of 25 to 30 hairs occupying two-thirds of its length. As the otocyst is open at this stage, it contains numerous otoliths, and these are either *in contact with, or attached to, the tips of these hairs*. Measurements of a number of these larval hairs were made in the Megalops and the stage succeeding it, and a comparison of these with the same hairs of adults is made in the following table:

STAGE.	Width of Otocyst.	Average Length of ten Hook Hairs.	Average Diameter of ten Hook Hairs.
Adult (30 cm. long)	1.96 mm.	49 μ	4 μ
Young crab	0.24 mm.	47 μ	4 μ
Megalops larva	0.21 mm.	46 μ	4 μ

This table brings out the interesting fact that the hook hairs of a Megalops larva, of a young crab and of an adult are of nearly equal size, although the otocyst of the adult is nearly ten times as long as that of the Megalops, and over eight times that of the young crab. On measuring the thread hairs to see if the conditions there were the same, it was found that in the adult they were three and a half times as long as in the Megalops stage; the thread hairs thus more than tripled their length, while the hook hairs remained constant. The number of hook hairs is approximately the same in the Megalops otocyst and in the sac of the adult. Their arrested development may be explained by the fact that they are true otolith hairs; when the otocyst becomes permanently closed, otoliths can no longer enter the sac, and these hairs, as they lose their original function, do not grow *pari passu* with the other hairs of the otocyst, but remain unchanged. They do not degenerate and become entirely functionless, for they are still innervated in the adult crab, and, though sac after sac is shed and new ones formed without an otolith's finding its way into the organ, they still retain the peculiar form of the original otolith bristles.

We are thus led to regard the hook hairs of the crab as homologues of the otolith hairs of *Macrura*, and for these five reasons:— (1) The similarity in their structure. (2) Their similarity in position at the posterior end of the sac. (3) Otoliths are in contact with the hook hairs in larval stages, though not in the adult. (4) When the otoliths disappear, the development of the hook hairs is arrested. (5) Gland pores open through the chitin of their cushion, as they do through that of the crayfish and lobster, although they are not found in the other sensory regions of the sac.

(2) *The thread hairs* are the largest, the most highly differentiated, and probably the most active sensory bristles of the otocyst. There are about thirty of them, arranged upon the large anterior sensory cushion in a regular row (Fig. *A, set. fil.*). These hairs are extremely attenuate. Measuring only two or three μ at the base, the straight or slightly bending shaft averages 320μ in length; it is unfringed save at the very tip, where for a short distance it bears two rows of extremely delicate pinnules. A peculiarity of this fringed tip is that it is not a continuation of the main shaft of the hair, but seemingly a diminutive hair in itself, sprouting from the latter. It makes a slight angle with the main shaft, the end of which projects a short distance beyond the base of the offshoot (Plate 10, Figs. 53, 54). The shafts of these hairs are directed out laterally, and slightly posteriorly, into the fluid contents of the sac, and they are so delicately attached at their bases that the slightest jar imparted to the liquid in which they float is sufficient to set them swaying. In alcoholic material they break off very easily. The shaft decreases somewhat in diameter towards its base and then suddenly enlarges. This enlargement is attached to the floor of a deep cup-like socket, the orifice of which is large enough to give ample play to the shaft in its movements (Fig. 53).

Straight attenuate hairs are found in the otocyst of the *Megalops* larva having the same relative position in the sac as the thread hairs of the adult. These hairs are not in contact with otoliths, but each shaft is fringed with filaments throughout its whole length. They become differentiated in later stages into the peculiarly modified thread hairs. Hairs similar to those of the *Megalops* larva just described are also found in the otocyst of the adult lobster, situated on the median wall of the sac and projecting free into its lumen. They are similar in both larva and adult, and are probably in function accessory to the otolith hairs. They may be homologues of the thread hairs,

which, in the crab, with the disappearance of the otoliths, have taken on the chief functional activity of the otocyst, formerly vested in the hook hairs.

(3) *The group hairs (set.)* form the third and most numerous class of the otocyst bristles of *Carcinus*. Irregularly distributed in the most lateral corner of the sac (Fig. *A*,) on a flattened portion of the wall ventral to the closed margins of the aperture (Plate 9, Figs. 42, 47; Plate 10, Fig. 55), they are unlike any of the otocyst hairs found in *Macrura*, being short, thick, and blunt, without a trace of fringing filaments (Plate 10, Fig. 49). They are $110\ \mu$ to $135\ \mu$ long and $12\ \mu$ to $14\ \mu$ in diameter. There are nearly 200 of these hairs, forming one large irregular group. They do not occur in the *Megalops* otocyst, therefore they must be developed at some later period. They may possibly be degenerated tactile hairs which in the formation of the otocyst have been folded into its cavity. Their proximity to the aperture of the otocyst makes this supposition highly probable. Their shafts are set into depressions in the sac wall, and, like the other otocyst hairs, they can sway freely on their bases.

d. Formation of Hairs. The hairs are formed in *Carcinus*, and in the *Brachyura* generally, after the method already described in *Palæmonetes*. From the presence of a cup-like depression at the base of each shaft, instead of the large spherical membrane found in the *Macrura*, it might be inferred that the cup results from the incomplete evagination of the hair.

e. Otoliths are entirely wanting in the adult otocyst, but are present in those larval stages where the sac is still open. They consist, as usual, of grains of sand, which in this case are very small, for the sac itself in these stages is less than 0.3 mm. in length. They can readily be introduced into the otocyst of the *Megalops*, as its aperture is relatively large. When in a succeeding stage the sac is cast off with its otoliths at ecdysis, the aperture of the new cyst closes at once, and no foreign particles can enter it; henceforth it is without otoliths.

2. Innervation of the Otocyst.

The general course of the otocyst nerve is shown in Plate 10, Figure 55 (*n. ot.*). As in the forms previously described, the sac lies in close proximity to the brain, and its nerve is consequently short. It is given off with the antennular nerve from the anterior end of the central organ, and its course for a short distance is directly lateral, until the base of the antennule is reached. At this point the antennular

nerve (*n. at.1*) turns straight forward, while that of the otocyst divides into three branches (Fig. 55, *n. ot.*, *n. ot.1*, *n. ot.11*). The most median and largest of these runs forward to supply the thread hairs; the middle branch goes directly to the posterior sensory cushion, which bears the hook hairs; while the third and lateral offshoot takes a nearly straight course along the posterior wall of the sac and supplies the tactile hairs of the antennule, and possibly the group hairs of the otocyst. The ganglion cells of the hook hairs are some distance posterior to the hairs and arranged in an irregular scattering group (Plate 10, Fig. 50, *cl. gn.*). Those of the thread hairs are lateral and posterior with reference to their hairs, lying immediately beneath the hypodermal cells of the sensory cushion, and forming an irregular single row, which is nearly parallel to the row of thread hairs (Plate 10, Fig. 53, *cl. gn.*).

a. Number of Nerve Elements to a Single Bristle. The nerve elements of the thread hairs were brought out clearly and completely by methylen blue and by Vom Rath's platinic-chloride method. The conditions found in a number of preparations are shown in Figure 53, where there is but a single element for each hair. This particular preparation was obtained with methylen blue, but the results were verified by Vom Rath's method. Counted in serial sections, the number of hairs and ganglion cells were approximately equal.

By the same method of counting, the elements of the hook hairs gave like results. In one case there were thirty hairs and thirty-one cells. No ganglion cells could be made out near the group hairs, nor any fibres supplying them. Certain clusters of cells are found directly beneath their bases, but their large peripheral processes, irregular outlines, and lack of central fibres marked these as matrix rather than nerve cells.

Here in *Carcinus*, then, as in the macruran forms described, *there is but one nerve element to each otocyst hair.*

The distal segment of the antennule was by chance sectioned in making preparations of the otocyst, and when stained with iron hæmatoxylin, the innervation of the *olfactory* hairs found in that region was sharply brought out (Plate 10, Fig. 52). As in the examples of this type of hair already described, a large spindle-shaped group of about 100 ganglion cells sends a strand of nerve fibres to the base of each shaft. These cells are relatively small and situated 0.5 mm. posterior to the hairs they supply. In Figure 52 a single nerve element is shown diagrammatically in black.

b. Peripheral Terminations. As seen in Figure 53 (Plate 10), the terminal fibres going to the thread hairs enter the pore at the base of the cup-shaped depression, pass up into the enlargement of the hair shaft, and there end free. In fact, there is in these hairs no functional necessity for the further continuance of the fibre into the shaft. Since the hairs project free into the liquid of the sac, if the otocyst is jarred or tilted, the shaft does not itself bend, but sways backward and forward upon its base. It is therefore at the base that the stimulus must manifest itself, and it was there in every case that the fibres were found to end.

In the olfactory hairs, on the other hand, the nerve fibres continue up into the large hollow shafts for some distance (Plate 10, Fig. 52, *set. olf.*). The olfactory hairs of *Carcinus* thus differ in their innervation from those of the otocyst, both *in the number of nerve elements* supplying each hair, and *in the peripheral nerve endings*. In the bristles of the otocyst there is but a single nerve element, and it ends free at the base of the hair without branching. In the olfactory hairs there may be a hundred elements or more which end in the shaft of a single hair.

c. Central Terminations. Entering the brain in front of, and just median to, the globulus, and ventral to the optic centres, the fibres of the otocyst nerve run straight back and enter the fibrillar mass (Plate 10, Fig. 55, *n'pil. at.1*), called "the neuropil of the first antenna" by Bethe ('97), who has described the central endings of the antennular nerve of *Carcinus*. The fibres of the antennular nerve end in a connected neuropil just median to those of the otocyst. Bethe judged from his physiological experiments that there should be certain fibres from the otocyst ending in the globulus. He was not able to demonstrate such endings with methylen blue, nor was there any evidence of their existence in my preparations. According to Bethe the fibres from the otocyst end by the separation of their fibrillæ in the neuropil. Lack of fresh *Carcinus* material prevented the verification of his work, but I have described similar conditions in the shrimp and crayfish.

d. Histology of the Nerve Elements. As the finer structure of the elements of the central nervous system has been fully described by Bethe ('98), it is unnecessary for me to say anything on that matter, and only a few words need be added here as to the histology of the peripheral nerves and cells. The peripheral nerve fibres are much smaller than in *Palæmonetes* or *Crangon*, and are without a myelin sheath. The peripheral ganglion cells are relatively large, averaging $12\ \mu$ in diameter. They are of the typical bipolar form, and are much elongated (Plate

10, Fig. 50, *cl. gn.*). Their nuclei are nearly spherical, and contain at least one large deeply staining nucleolus. No special preparations were made for the purpose of demonstrating fibrillæ in either nerve cells or fibres. Bethe found them in all fibres, and traces of them in the cells of the brain.

3. *Development of the Otocyst.*

For the purpose of comparison with development in the lobster, the antennules of the first five free swimming larval stages of *Carcinus* were dissected out, stained and examined *in toto*. By this means it was ascertained that *there is no functional otocyst in the Zoea stages.*

(a) *The first Zoea* shows no trace of invagination in its antennule. There is, however, an aggregation of nuclei beneath the chitin of the region where the otocyst is to appear.

(b) *The second Zoea* shows a slight depression on the dorsal side of the antennule, and its basal portion has begun to widen.

(c) *In the third Zoea* this widening has increased, and the lateral wall of the antennule has now formed a rounded protuberance. The invagination has increased in size and depth, but no hairs nor otoliths are yet contained in it.

(d) *At the Megalops stage* we find that a sudden development has taken place, as in the fourth larval stage of the lobster. The Zoea has by a single moult become metamorphosed into a Megalops, and the otocyst changed from a shallow depression to a nearly closed sac, containing sensory hairs and otoliths. Two sensory cushions are present: one of these, posterior and median, bears 25 to 30 hooked hairs, upon the tips of which otoliths rest; the other prominence projects from the anterior portion of the median wall, and bears a vertical row of about 30 hairs, the shafts of which are directed laterally. These hairs are long, attenuate, and well fringed with delicate filaments. They do not come into contact with the otoliths, and, as already noted, they develop into the thread hairs of the adult; those of the first sensory cushion described correspond to the hook hairs of the mature crab. The third type of hair found in the adult is not developed at this stage. The aperture is anterior and lateral in position, and extends transversely across the antennule.

(e) The next stage examined was that of a young crab probably of the stage immediately succeeding the Megalops larva. The otocyst is slightly larger, and its opening is already nearly closed. As a result, only a few small otoliths were contained in it.

The otocyst of *Carcinus* thus resembles very closely in its development that of the lobster. In both there is no trace of the organ in the newly hatched larvæ, and for three successive moults it is not functional. In the fourth larval stage, with a sudden metamorphosis of the animal's general form, the otocyst is also rapidly changed from a mere depression to an active, well-developed organ. The significance of these sudden correlated transitions will be seen when the otocyst is considered physiologically.

C. THEORETICAL CONSIDERATIONS.

1. Comparison of the Otocyst with the Vertebrate Ear.

The otocyst has been compared by many investigators to the auditory organ of vertebrates. Leaving their functions entirely out of account, how far do the two correspond in structure?

The otocyst of *Macrura* consists of an open sac, a sensory prominence, bristles, and otoliths resting upon them; essentially the same conditions as are found in the ear of *Myxine*, though the latter has five sensory regions instead of one. The otocyst of macruran decapods might thus be well compared to an isolated ampulla in the ear sac of *Myxine*, and the sensory cushion to a single crista acustica.

In the *Brachyura* the organ is still more highly differentiated. The sac is closed, there are three sensory regions, and the hairs found on them project free into the lumen of the otocyst; otoliths are entirely wanting. The structure of the sensory apparatus is in this case similar to that of the cristæ of higher vertebrates, and the sac itself resembles the utricle. But *there is no portion of the decapod otocyst so differentiated as to bear more than a fancied resemblance to the semicircular canals, the middle ear, or the cochlea of higher vertebrates.*

Each crista acustica in vertebrates, however, is made up of separate elements, which may be compared to the sensory elements of the otocyst. Every auditory hair of the crista is developed from the exposed end of a specialized epithelial sense cell, which itself forms the basal part of the hair, and is supported in position by the other cells of the epithelium. It has been shown by both Retzius ('94) and Morrill ('98) that these epithelial sense cells of the cristæ in vertebrates are not true nervous elements, as the auditory fibres are not continuous with them. Both the cell and its auditory hair taken together are to be compared to the bristles of the otocyst, in that they constitute a non-nervous end-organ.

Their innervation is also essentially the same. In the vertebrate crista an auditory nerve fibre passing from the brain is connected with a bipolar nerve cell in the auditory ganglion, from whence its peripheral fibre extends to one of the epithelial sense cells, ending with a slight enlargement in close proximity to, or in contact with its base. *The single fibre supplying each end-organ is never directly connected with the cell, nor does it ever run through it to the hair itself.* The only difference between the peripheral endings just described, and those of the otocyst, is that in the hairs of the latter the fibres end free in the base of the hollow shaft, at the point where, from the structure of the hair, the greatest stimulus would be produced; while in the vertebrate end-organ the nerve process is applied to the convex under-surface of the basal cell, which would transmit stimuli with an equal degree of intensity to fibres in contact with it at any point.

The otoliths of the vertebrate ear are formed by secretion, while those of the crustacean otocyst are largely granules of sand taken into the sac from the exterior. In some Crustacea, however, such as the Mysidæ, and in many other invertebrates, the otoliths are formed within the sac.

In all decapods the innervation of the otocyst hairs distinctly differs from that of the olfactory bristles, not only as to peripheral terminations, but also in the number of nerve elements supplying each hair. As has been previously noted, the stimulus is transmitted by specialized cells or hairs to the nerve fibres of both the otocyst and the vertebrate ear, and is never applied *directly* to their endings. In either case *only one nerve element* is usually in contact with the terminal sense cell, and this is apparently ample to carry the isolated nervous message to the brain.

With the olfactory sense it is different; in both vertebrates and Crustacea the chemical stimuli which produce the olfactory sensations act directly upon the nerve cells or their terminal fibres. In vertebrates portions of the nerve cells are exposed at the surface of the olfactory epithelium. In crustacea peripheral fibres from the ganglion cells of the olfactory nerve end free in the hollow, perforate bristles. In Nereis and the earth-worm, Langdon ('95, '00) has shown that the processes of the olfactory cells end free upon the surface of the cuticula, and completely exposed to chemical stimuli; a similar condition has been shown by Lewis ('98) to exist in two polychætous worms of the family Maldanidæ.

The large numbers of nerve elements ending in each olfactory tube or bristle of decapod Crustacea may be accounted for by the fact that

the stimulating chemical substances occur as slight traces only. In order that a sensation may be perceptible, apparently a large number of olfactory elements must be stimulated at once, for the larger their number, the stronger should be the sensation produced. The olfactory bristles are located on the flagella of the antennules, a position most favorable for the reception of chemical stimuli, as the flagellum projects some distance in front of the animal and can be kept in constant motion. The number of the bristles is limited on account of the small surface to which they are necessarily confined, so that, if thousands of olfactory fibres are to function simultaneously, large numbers of them must be exposed to the chemical stimulus in the same hair. It is possible, too, that different nerve elements may be affected by different substances in solution; and that consequently many olfactory elements are necessary for each hair, in order that different chemical stimuli may be perceived.

2. The Neuron Theory.

The conditions found in the sensory nerve elements of the otocyst are favorable to the neuron theory, in so far as they confirm the generally accepted idea that the nerve fibres are each differentiated from a single nerve cell, and that fibre and cell taken together form a trophic unit. This conclusion is borne out not only by the structural conditions already described, where each fibre is connected with only one peripheral ganglion cell, but also by an experiment which I made by severing the otocyst nerve proximal to its ganglion; in this case after the lapse of a few weeks degeneration of the sensory fibres took place back into the brain.

As to the modifications of the neuron theory recently proposed by Apáthy ('97) and Bethe ('98),—that the neurons are connected by fibrillæ,—the fibrillar structure of the fibres is confirmed by my preparations, though no fibrillæ could be demonstrated in the nerve cells. In regard to the definite connection of the neurons with each other by continuous fibrils, such as Apáthy figures and describes in the Hirudineæ, my preparations gave no positive evidence; but the fact that the central fibrillations of the nerve elements of the otocyst could not be traced to determinate endings, makes it quite possible that such a direct communication between motor and sensory neurons may exist. While Bethe proved that there were more fibrillæ in a motor fibre than extended into its central ganglion cell, and also, that some fibrillæ entered the fibre by one branch and at once passed out by another, in no case did he trace

a single fibril from one neuron into another. If such a connection between nerve elements had been demonstrated beyond a doubt, they might still be considered as distinct trophic units, and the interdigitating fibrils uniting them as the products of separate neuron cells. In the light of the important discoveries of Apáthy and Bethe, however, the old view, that the nervous impulses are transmitted from sensory to motor neurons by the simple contiguity of their dendritic processes, may have to be abandoned for the more reasonable assumption of direct fibrillar communication.

PART II.—PHYSIOLOGY.

As Bethe has well said, the best of anatomical knowledge concerning an organ cannot be taken as certain evidence of its functions. It is only after these functions have been experimentally demonstrated, that we may ascribe them with confidence to the organ in question.

Have we, then, any experimental proofs that the decapod Crustacea hear? If so, is the otocyst the auditory organ; if not, what is its function? These are the three chief questions which I shall attempt to answer.

A. HISTORICAL SURVEY.

Up to the time of Delage ('87) the auditory function of the otocyst was accepted, and that alone.

Minasi (1775) promulgated the idea that Crustacea could hear. The hermit crab, *Pagurus*, was more sensitive than man to sound vibrations. The tones of a distant bell, the striking of a clock, were, according to this worthy monk, perceived by *Pagurus* sooner than they were by him.

Ælianus (1784) notes that the fishermen of his time took *Pagurus* by means of music.

All the older zoologists have regarded the otocyst as an organ of audition.

Hensen ('63) was the first to get experimental data. From the anatomical conditions found in the otocyst of the lobster, he argues as follows: Here are 468 auditory hairs upon which otoliths rest. Of these hairs no two are of the same size; they vary in a nearly continuous series from 0.72 mm. to 0.14 mm. in length; thus the volume of the largest is to that of the smallest as 140:1. Comparing these

ratios to those of the volume of organ pipes, we should have, *if the hairs responded to different sound vibrations*, an auditory organ with a range of three octaves.

To prove that his hypothesis was correct, sound waves were conducted, by a mechanical contrivance modelled after the middle ear of mammals, into the water of a vessel containing *Mysis*, the so-called auditory hairs of which were under observation by the microscope. When notes of a certain group were sounded on a musical instrument, a certain hair would vibrate and disappear from view. Others would also respond, but each to different sets of notes.

Having proved that the different hairs responded to different sound waves, Hensen next determined that Crustacea would react to vibratory stimuli. A resonant bar of wood was floated in a vessel containing free-swimming individuals of the genera *Mysis* and *Palæmon*. When the bar was struck, both forms responded by a strong leap away from the source of the sound. *Palæmon* reacted even more strongly when rendered sensitive by gradual strychnine poisoning.

Milne-Edwards ('76), Jourdain ('80), Delage ('87), and many others have accepted the sense of audition in Crustacea as a fact.

Garbini ('80, p. 192) uncritically remarks: "Che i crostacei odano è indubitato; lo sanno anche i pescatori, i quali devono avvicinarsi loro in silenzio" (That crustacea hear is undoubted; this the fishermen know well, who, when they capture them, approach in silence).

Individuals of *Palæmonetes varians*, which he kept in an aquarium, sprang backward at the slightest sound.

Delage ('87) was the first to discover another function than that of audition for the otocyst. By cutting off or destroying the sacs, he proved that they functioned also as organs of orientation. Animals so operated upon (*Mysis*, *Palæmon*, and *Polybius* among Crustacea) were unable to keep their normal upright position in swimming. Blinding intensified the effect, showing that sight aided in orientation.

The otocyst may therefore, in his opinion, be compared to the simplest form of the vertebrate ear, — that found in *Myxime*, — where the semicircular canals and utriculus serve the purpose of orientation, the sacculus that of audition (to intensity of sound). In the otocyst of Crustacea both functions are performed, he believes, by the same organ.

Verworn ('91) proved that the otocyst of *Ctenophores* served simply for orientation, not being sensitive to sounds.

Bunting ('93) confirms the conclusions of Delage as to the function

of the otocyst in geotropic orientation. When the otocysts of young crayfish were destroyed, especially if their chelæ were also removed to render their position in the water less stable, there was the same loss of power of orientation that had been observed by Delage.

Kreidl ('93), in order to avoid the disturbance to the normal condition caused by the removal of the otocysts, made use of the following ingenious experiment: *Palæmonetes* newly moulted, and thus without otoliths, were placed in filtered water to which iron filings were added. The otocysts were soon filled with the metallic particles, the chelæ being used to convey them to the opening of the ear in the dorsal wall of the antennule. When now a strong electromagnet was held at one side of, and slightly above the sacs containing the iron otoliths, the shrimp would lean a little to one side, its dorso-ventral axis, normally coincident with the direction of gravity, pointing away from the magnet. This new position of the dorso-ventral axis is proved by mechanics to be the resultant of the two pulls, that of gravity and that of the magnet, the animal accommodating itself to the direction of the resultant of the two forces. If the magnet were held to the right of the animal, the otocysts would be stimulated in precisely the same way as by gravity alone when the shrimp's dorso-ventral axis is artificially turned toward the right; the result is that it attempts to recover its normal position with reference to gravity, and thus turns its vertical axis away from the magnet. Kreidl, going a step further than his predecessors, affirms that the otocysts are not auditory, but exclusively static in function. Thus they should be called *stato-cysts*, not *oto-cysts*.

Still further evidence as to their static function is supplied by Clark ('96). The compensation movements of the eyestalks of the fiddler crab (*Gelasimus pugilator*) and the lady crab (*Platyonichus ocellatus*) were observed. Tilting a normal animal about its antero-posterior axis gave a parallel compensating movement of the eyes through an angle of 35° to 45° , whether the tilting was to the right or left. On rotation about the dorso-ventral axis, no such movements are shown, though when rotated about the lateral axis, the animal's eyes moved in the opposite direction through an angle of 35° .

If both otocysts were removed, these compensative movements were much reduced, and the general movements of the crab also became very uncertain.

After removal of one otocyst 94 per cent of the animals showed on rotation toward the uninjured side less compensation than uninjured animals. Blinding produced only a slight reduction in the compensatory

motions, but when, in addition to this, both otocysts were destroyed, compensatory movements completely disappeared.

Bethe ('97), in his physiological work on *Carcinas mænas*, confirms Clark's results. In a previous paper he ('95^a) observes that *Mysis can hear after the otocysts have been destroyed*, but with difficulty; also that the animals are more sensitive to low tones than to high.

Thus, until 1898 three views were held as to the function of the otocysts:

(1) That they are purely auditory organs (Hensen and the earlier zoölogists).

(2) That they are both auditory and static in function (Delage and Bethe).

(3) That they are purely static in function, i. e. organs of orientation (Kreidl, Clark, and others).

To determine whether decapod Crustacea really hear, and if so, whether the otocyst is the organ of audition, is the aim of two papers by Beer ('98, '99).

In criticising the conclusions reached by Hensen and Bethe, Beer remarks in his first paper that, because decapods were made to react to different sounds, does not prove that these Crustacea responded to *true* sound, or that they heard. These reactions may have been due to their *feeling* vibrations transmitted to the water from the walls of the vessel in which they were confined, — a tactile reaction, or, to use Bethe's term, a "tango-reflex." Experiments with sounds produced in the air Beer considered superfluous, as it is a well-known physical fact that most of the sound waves are reflected from the surface of water.

Beer found that Crustacea reacted strongly to sounds produced in the water by striking partially submerged bells, jars, etc., but only when they were not at a greater distance from the source of sound than that at which vibrations could be detected by *the hand immersed in water*. The animals responded more strongly when near the walls of the vessel; but vibrations could be felt by the hand also in this position more distinctly, even though further removed from the source of the sound.

For animals well supplied with tactile organs, he regards pure sound or pure audition as impossible; because vibrations could be felt as soon as heard, and, this being the case, audition would be useless.

On removal of the otocysts, *Palæmon* and *Palæmonetes* still responded to sound waves produced in the water. There was, however, a slight inhibition of the customary reactions, therefore the hairs of the otocyst are probably slightly tactile as well as static in function.

From experiments on many different species of Crustacea, Beer ('98, p. 31) concludes: "Wir haben gute Gründe, dem in Rede stehenden Sinnesorgane der Krebse statische Functionen zuzuschreiben, und haben vorläufig gar keinen Anhaltspunkt, ihm Hörfunctionen, ja den Krebsen überhaupt Gehörsinn, zuzuschreiben."

Hensen's statement that the free auditory hairs of *Mysis* vibrated to different musical notes is simply an interesting physical fact. Hairs on the back of one's hand will do the same, but they are not auditory. The true sense of hearing is lacking not only in Crustacea, but probably in all other water-inhabiting animals lower than Amphibia, especially in invertebrates.

Beer thus comes back to the opinion of Johannes Müller ('37) expressed sixty years before: That in most invertebrates we find nothing comparable to the ear; and any reaction to sound vibrations should be attributed to a *tactile* rather than to an *auditory sense*.

A few months later Beer ('99) brought out a second paper, describing his experiments with blind shrimps, and answering a criticism of his previous work by Hensen ('99). Here the auditory sense, he urges, ought to be intensified, all possibility of sight entering as a factor into the experiments being effectually eliminated. The conclusions reached by him in his earlier work are verified in this.

General Criticism.

It is a noteworthy fact, that in the experimental work done to determine the function or functions of the otocyst, few of the investigators have acquainted themselves with the finer structure of the organ under consideration; one of the essentials for successful physiological work is a complete knowledge of the anatomical side of the subject. This is well illustrated in Bethe's work on the brain of *Carcinas*, where anatomical facts, obtained by means of methylen blue, laid the groundwork for his later confirmatory experiments.

Since the dissections by Hensen, little or no morphological work has been done on the otocysts of the Brachyura, yet a deal of physiological work has been attempted.

The experiments of Beer are beautifully worked out, and logical in sequence; yet, while he tried experiments on water-inhabiting animals, no attempt was made to experiment on amphibious decapod Crustacea, such as the fiddler crab. These animals, spending, as they do, a good share of their life on land, would certainly have more need of an auditory organ than decapods which are always beneath the surface of the water.

B. EXPERIMENTS AND OBSERVATIONS.

I. The Otocyst as an Auditory Organ.

That the responses of water-inhabiting animals to atmospheric sounds is nothing more than a myth, has been too well proved by Beer to need further investigation. The well-known physical fact that the larger part of the sound waves are reflected from a liquid surface is enough in itself to confute fables of fishes and crustacea hearing, and coming to be fed at the *sound* of a bell. But since in the case of responses of decapod Crustacea to sound vibrations conducted into the water, the experiments of Beer contradict Hensen's earlier results, repetition of Beer's work, though perhaps not absolutely necessary, may not be out of place.

METHODS.

The shrimps to be experimented upon (*Palæmonetes*) were placed in glass vessels 40 cm. in diameter and 20 cm. deep. Sound waves were conducted to the water by means of a steel pipe one inch in diameter and about two feet long, which was firmly clamped at its upper end and projected into the vessel containing the shrimps; a brass rod was in some cases substituted for the pipe. The pipe and rod were set into vibration either by striking them with a hammer, or by drawing across them, bowlike, a strap of rosined leather. Sounds were also produced by striking glass jars suspended in the water, and by striking the sides of the aquarium itself. The movements made in producing the sounds were completely screened from the view of the shrimps by pieces of cardboard placed over and at one side of the vessel, a small aperture being left for observing their reactions.

Palæmonetes could be made very sensitive to all nervous stimuli by leaving them over-night in sea water containing from 0.1 to 0.2% of sulphate of strychnia. This solution is fatal to a small fish (*Fundulus*) in five minutes; many of the shrimps die, but the sensory apparatus of those which remain alive is rendered abnormally acute. Blinding was accomplished by simply painting the eyestalks with a thick coat of lampblack and shellac; the otocysts were removed by means of a fine hooked needle, with scarcely any other injury to the animal.

1. Responses of *Palæmonetes* to Vibrations transmitted to Water.

a. Normal Conditions. Under normal conditions, when sound vibrations were transmitted to the water, normal animals responded by a

slight leap backwards or to one side, if the source of the sound was within a distance of 20 cm. If an animal happened to be near the side of the vessel, and the sound was produced near the opposite wall 40 cm. distant, the response would be, *not a darting away from the source of the sound*, but a leap back from *the side of the vessel toward the source of the sound*. Again, if an animal was facing the side of the aquarium with its antennæ in close proximity to it, and the opposite wall was sharply tapped with the finger-nail, or lightly with a hammer, the shrimp, as before, sprang away from the side of the vessel *toward the source of the stimulus*. The response was usually well marked, a leap of from 10 to 15 cm. being made.

b. Poisoned with Strychnine. The responses obtained were invariably much stronger and more uniform with animals poisoned by strychnine in the manner stated above, than with normal shrimps. In other respects they were the same, and served merely to emphasize the results obtained by the first experiments. Blinded individuals showed practically the same reactions, but to make sure that the factor of vision was effectually cut out, the eyestalks of the shrimps in the succeeding experiments were all painted.

c. Both Otocysts removed. Of animals from which both otocysts had been removed, all but one gave a more or less strong response to the sounds conducted into the water in which they were swimming. The reactions were not as marked, nor could they be produced at as great a distance from the source of the sound, as in the case of normal animals. Nine individuals were affected by the stimulus when at a distance of about 10 cm.; the rest, only when in still closer proximity. A slight jar imparted to the walls of the aquarium produced essentially the same responses as the transmission of sound to the water by means of the vibrating pipe or rod. Removal of the otocysts has, therefore, only a very slight inhibitory effect upon the responses called forth by sound-wave stimuli in normal or strychnine-sensitized animals.

d. Removal of Antennæ and both Antennules. The removal of the antennæ and antennules, which bear large numbers of delicate *tactile* hairs, very much reduced the reaction of the shrimps to these vibratory stimuli. Only when an animal was in close proximity (5 cm. or less) to the source of the sound, or in contact with the walls of the vessel, would it respond, and then only feebly. Slight jarring of the aquarium produced no reaction, unless some part of the animal's body directly touched the sides or bottom of the jar, or was in contact with the sound-producing instrument.

The above experiments were duplicated on *Crangon vulgaris* with similar, though less marked results, as Crangon is much more sluggish than Palæmonetes.

A third set of experiments was tried with *Virbius zostericola*, a shrimp-like decapod *without otocysts*. Normal animals responded vigorously on striking a glass jar partially submerged beneath the water in which they swam. This response, much increased by strychnine poisoning, was distinctly diminished when both antennæ and antennules were removed.

e. Meaning of these Experiments. All of my experiments confirmed the conclusion of Beer, that free-swimming decapods, whether possessing otocysts or not, will respond to stimuli which are transmitted to them by the liquid medium they inhabit. The next question is, to determine whether this response is caused by the perception of *sound* waves or by the coarser vibrations or jars imparted to the water. In other words, have we to do with true *audition* or with the *sense of touch*?

Beer has clearly shown that there is no such thing as the transmission of pure sound waves from air to water. Coarser waves are imparted to the liquid simultaneously with those of sound, and can readily be felt by the immersed hand.

After making a number of trials with sounds produced as in the preceding experiments, I ascertained that the vibrations not only could be plainly felt by the submerged hand, but also that they could be felt *at a distance from 10 to 20 cm. greater than that at which the shrimps would react*. This fact does not at all prove that the animals experimented with do not hear, but merely shows that the responses supposedly produced by sound stimuli may be simple tactile reflexes, called forth by vibrations which, since appreciable to the immersed fingers, we may certainly assume to be *felt* by these animals, so well supplied with delicate tactile organs.

That the reaction is really due to tactile stimulus rather than to audition, is indicated by several facts brought out by the experiments:

(1) Animals, when near the wall of the vessel, even though distant from the source of the sound, respond vigorously, *leaping away from the wall and toward the sound*. The wall is set into vibration by the production of the sound, and it is apparently this vibration which affects them, rather than the true sound-waves imparted to the water.

(2) The average distance from the source of the sound at which they will respond is less than that at which vibrations may be felt by the hand.

(3) Removal of the antennæ and antennules which are supplied with numerous *tactile* bristles, inhibits the reaction.

(4) Decapods, such as *Virbius*, normally without otocysts *respond vigorously*; but removal of antennæ and antennules diminishes their sensibility in a marked degree.

(5) Precisely the same responses as were called forth by the production of sound were also obtained by simply tapping or jarring the walls of the aquarium.

Whether due to tactile stimulus or to audition, the fact remains, that the otocyst has little or no part in producing the reactions observed in the series of experiments; for (1) decapods normally without otocysts respond as vigorously to the same stimuli as those possessing them, and (2) the removal of the sacs from the latter has only a very slight inhibiting effect, which might be due either to the loss of these organs, or to the injury of the nerves supplying the many tactile bristles of the antennule.

Consequently, the otocyst not being the organ by stimulation of which responses to sound vibrations are called forth, and there being no other sensory apparatus in Crustacea especially differentiated for the reception of sound waves, we are led to the conclusion that in decapod Crustacea a true auditory organ is wanting.

The acute tactile sense of decapods may to some extent serve the same purpose that audition does in vertebrates. In mammals the senses of touch and hearing grade into each other. The range of the average auditory organ in mammals is from 30 to 16,000 vibrations per second; waves of less than 30 vibrations per second do not usually produce auditory sensations, but are appreciable to the tactile sense. It is important to note that decapods respond most vigorously to low notes, and not at all to high notes or sounds produced by very rapid vibrations. This fact would seem to be good evidence that the vibrations imparted to the water and perceived by decapods correspond to those which produce tactile rather than auditory sensations in vertebrates.

2. Responses of *Gelasimus pugilator* (*Brachyuran decapod*).

a. *To Vibrations transmitted to Water.* On the conduction of sound waves to water by the same means as in the preceding experiments, these fiddler crabs responded, but by no means as vigorously as did the *Macrura*. They always rested upon the bottom of the aquarium, and reacted by retiring slowly, either from the source of the sound, or from the vibrating walls of the aquarium. In either case the response took

place only when the animal was within a few centimetres of the vibrating surface, and was most marked when the antennæ and antennules were in close proximity to it. After blinding the animals and removing their otocysts, no apparent difference could be detected in the reactions called forth, as compared with those of normal crabs; removal of the first two pairs of appendages caused, on the contrary, the responses to almost completely disappear.

b. To Atmospheric Sounds. As the fiddler crab is on land a large part of the time, a number of experiments were tried to determine the effect of aerial vibrations upon them when they were feeding under perfectly normal conditions. A position for observation was selected near a bank which was completely honeycombed by their burrows, where one could see the animals perfectly well, and yet be screened from their view by intervening bushes. If one remained perfectly motionless, the animals would come within a short distance of the observer's place of concealment, feeding as unconcernedly as if no one were near. When a number of crabs were little more than five feet distant, a horn was blown, care being taken to direct it away from them. Although a sound was thus produced loud enough to be heard at some distance, all the animals continued to feed undisturbed.

The striking together of two stones, and the sound produced by striking an iron pipe with a stone (the objects in both cases being held in the hand) also had no effect upon them. On striking the ground with a heavy stone all the crabs within a radius of ten or twelve feet were startled; some of them merely stopped feeding, while others scuttled into their burrows. The same result was brought about by simply stamping upon the ground. If a quick movement was made in the sight of the animals, they at once scattered precipitately to their holes. These observations were repeated a number of times, and on crabs of two different localities, with the same results.

From these experiments and observations, we may draw the conclusion that the fiddler crab, whether in water or on land, does not respond to true sound-stimuli, but is affected only by jars or vibrations transmitted to the water or to the ground. In neither case can they be said to hear. When feeding upon land they do not depend upon an auditory sense to protect them from terrestrial enemies, but rely entirely upon their keen vision and delicate tactile organs.

The statement is generally accepted, that all animals which produce sounds also have a sense of hearing, and this is advanced as an argument in favor of audition in Crustacea. The two well-known examples

of sound production among decapods, observed by T. Parker ('78) and Goode ('78), are (1) the stridulation of the rock lobster, *Palinurus*, where the sound is produced by rubbing the second segment of the antenna against the antennule, and (2) the pistol-like report produced by *Alpheus* in snapping together the claws of the great chela. As Beer has pointed out, the otocyst is poorly developed in *Palinurus*; furthermore, no individuals of either species have ever been observed to respond in any way when these snappings or stridulations were produced.

We can no more argue, from these two instances of sound production in decapods, that there is an auditory function in all Crustacea than we can that all fish hear because the drum-fish makes a sound.

The enemies of water-inhabiting crustaceans produce no sounds which would reveal their presence to their prey; the latter would therefore have to rely upon other forms of stimulation for the detection of their foes. Even if it were admitted that they possessed a sense of hearing, yet, as shown both by Beer's experiments and by my own, it must be so restricted in range that they would be able to detect sound produced at no greater distance than that at which the vibrations could be felt by the hand. Such a dull sense as this would be of no practical value in protecting crustaceans from their foes.

Both observation and experiment lead, then, to the following general conclusions:

(1) The reactions formerly attributed to sound stimuli are nothing more than tactile reflexes.

(2) The otocyst has little or no part in calling forth these reactions.

(3) There is no direct evidence to prove that decapod Crustacea hear, and until such evidence has been obtained, we are not warranted in ascribing to the otocyst a true auditory function.

II. The Otocyst as an Organ of Equilibration.

All water-inhabiting, free-swimming animals which maintain a definite position with reference to gravity either during locomotion or when at rest, can thus orient themselves only under one or the other of two conditions:

Either the animal must be normally in a condition of stable equilibrium, keeping its definite position under the influence of gravity like any inanimate body; or, if a position of unstable equilibrium is maintained, the animal must in some way be made sensible of the direction of gravity, and must keep itself in equilibrium by its own efforts.

In the first case merely the mechanical action of gravity is called into play; in the second instance, besides the outside action of a physical agent, a subjective sense of direction and orientation is involved.

In free-swimming decapods the body, moving or at rest, is in a position of unstable equilibrium. The dorsal side being always kept uppermost, the centre of gravity is high up, and a dead individual or an inanimate object of the same size, form, and disposition of weight would at once turn over. These animals must then by some means be rendered sensible to the direction of gravity, in order to be able to maintain a definite position of unstable equilibrium with reference to it. To determine what are the organs which perform the function of equilibration, the following means have been employed in the present investigation:

(1) Removal, or prevention of the action of an organ, and observation of the effects on the equilibration of swimming or walking decapods.

(2) Observation of the effect of such removal on the gimbal-like movements of the eyestalks (compensation movements) when the animal is rotated about its different axes.

(3) Observations on the orientation of animals normally without otocysts.

(4) The effect of the development of the otocyst on the equilibration of the free-swimming larvæ.

(5) The effect on equilibration of the addition of magnetic attraction acting on the otocyst at right angles to the pull of gravity.

In these experiments blinding was accomplished by painting the eyestalks with a mixture of lampblack and shellac. The otocysts were removed under the lens of a dissecting microscope with the aid of a fine needle, bent in the form of a hook. Other parts, such as flagella of antennæ and antennules, were simply cut off with a pair of fine scissors. *Palæmonetes vulgaris*, being hardy, was the species chiefly employed, but experiments of a like nature were also carried on with *Mysis*, *Crangon*, and *Gelasimus*. A large number of trials were made with each species. When organs were cut off or destroyed, the animals so operated upon were kept under observation for from 15 to 25 days, and the experiments were then repeated, in order to make sure that the effects observed directly after the operation were not due to abnormal conditions produced by nervous shock.

1. *The Removal of Sense Organs and its Effect on Equilibration.*

The normal position in which a shrimp, like *Palæmonetes*, holds itself while swimming, is very characteristic:

(a) The dorsal side of the body is always kept uppermost, its dorso-ventral axis corresponding to the direction of gravity, and its long axis usually lying in a horizontal plane.

(b) Shrimps can be overturned only with difficulty, and even if this is accomplished, they right themselves at once.

(c) Animals coming to rest upon surfaces not horizontal tend to keep themselves in the horizontal plane, but with the dorsal side always up.

a. Eyes blinded. Nearly fifty animals were operated upon in this way and their movements observed. Placed in an aquarium, they swam about indiscriminately, but always with the dorsal side up, there being little if any rolling from side to side. They were not easily overturned artificially, and when interfered with, righted themselves quickly. The most noticeable difference to be observed between their movements and those of normal animals was the tendency to remain quiet and to hold fast to any object with which they came into contact, thus substituting the sense of touch for that of vision lost. It is apparent, therefore, that some organ or organs other than the eyes play the chief part in equilibration.

b. Both Otocysts removed. Twenty-five animals were operated upon by removing both otocysts. In swimming there was still a strong tendency to keep the dorsal side uppermost, but there was in every case marked rolling from side to side, which occasionally culminated in a complete rotation about the long axis of the body. The animals could be easily overturned, and though they strove to right themselves, it was not accomplished as soon nor as accurately as in normal or blinded shrimps. They were more apt to remain quiet, or to swim along upon the bottom of the aquarium, than to swim free. If the long flagella of the first and second antennæ were removed, rolling motions were increased and also the difficulty in righting themselves if overturned, the flagella being probably used as balancing organs in equilibration; but the extirpation of the otocysts alone brings about a marked loss of orientation, much more pronounced than that produced by simply blinding.

c. Both Eyes blinded and both Otocysts removed. Upon removal of both otocysts and blinding of both eyes, entire loss of the normal

position in swimming resulted in twenty-one trials out of the twenty-five made. The animals turn over and over, rotating about the long axis, now in one direction, now in the other; they also pitch forward and backward about their transverse horizontal axis, and often swim upon their backs. They do not resist overturning, unless holding to some stationary object, and make no attempt to right themselves when swimming free. The moment they come in contact with a horizontal surface, such as the bottom of an aquarium, they at once take up their normal position, righting themselves quickly, but if the surface they touch be oblique or vertical, and even if they come in contact with the under side of a horizontal surface, they cling to it tenaciously, taking up a position *with reference to the plane of contact*, and not in relation to the direction of gravity, as is the case with normal animals. Thus the phenomena of orientation completely disappear in the majority of cases when both otocysts and eyes are rendered functionless, at least in the free-swimming animal. When the animal comes in contact with solid objects, the sense of touch asserts itself and the phenomena of orientation are again, to a certain degree, made manifest.

d. One Eye blinded, both Otocysts removed. The conditions here are essentially the same as when only the otocysts are extirpated. There is a well-defined rolling motion in swimming, and if overturned artificially, the animal is very slow in regaining the original position.

e. Both Eyes blinded, one Otocyst removed. In such experiments no effect was produced different from that brought about by blinding alone. There was no evidence of a tilting of the dorso-ventral axis toward the injured side, as might be expected, if the functions of the two otocysts were co-ordinated. Nor was there during swimming a rotation toward the side from which the otocyst had been removed. We may therefore conclude that in the phenomena of equilibration each otocyst, as well as each eye, acts independently.

As check experiments, both antennules were removed *distal* to the otocysts. No abnormal conditions were produced in swimming movements, the wounds healed, and these individuals lived in aquaria as long as normal animals. Where the otocysts were extirpated, individuals were kept as long as four weeks, and after this interval, when blinded, they gave the same evidences of loss of orientation as they did immediately after the operation.

These observations, made upon *Palæmonetes*, were found to hold true also for *Crangon*, *Mysis*, and lobster larvæ. Experimentation with the

fiddler crab gave like results. If blinded and deprived of otocysts, the crabs rolled both forward and backward when walking or running; this effect was still more apparent when the animals were placed in the water.

2. *Removal of Sense Organs and its Effect on the Compensation Movements of the Eyes.*

The following experiments, carried out on *Gelasinus pugilator*, confirm the work done by Clark ('96). When a crab is tilted to the right or left, forward or backward, the eyestalks tend to keep their original directions, thus seemingly moving through a certain angle. Such movements, which have been observed also for the head and eyes of many vertebrates and insects, are called compensation movements, and the angle of movement, the angle of compensation.

The angle of compensation in the fiddler crab was measured by means of the apparatus described by Clark ('96), a small table to which the animals could be securely fastened and tilted about their chief horizontal axis. A scale ruled to degrees enabled one to read accurately the angle of compensation, and the angle through which the animal was turned. The long eyestalks of the fiddler crab make it easy to determine the angle of the eye movements.

The angle through which the animals were turned was in all cases 45° first to the right, then to the left, about the chief, or longitudinal axis of the body. In each experiment fifty animals were used, the average being taken as the angle of compensation. These animals were most of them kept twenty days, and the angle then measured again, thus guarding against abnormal conditions.

a. *Normal Animals.* In normal crabs the eyestalks are so held as to make an angle of about 22° with the vertical. The eye movements are always correlated, and if the animal's body is tilted to the right (45°) the right eye makes a compensating movement of 18° upward, the left eye one of 25° upward; rotated to the left, the conditions are just reversed, the right eye now moving through an angle of 25° . The movement of the eye of the side toward which the animal is rotated is in each case less by about 7° than that of the other eyestalk. This is due to interference of the carapace with the eyestalk, preventing its passage through a greater angle.

b. *Both Eyes blinded.* Tilting either to right or left had the same general effect as in normal animals, but the right eye described an arc of only 13° , the left eye one of 20° , or *vice versa*. There is thus a

marked reduction in the angle of compensation, a decrease of about 5° , as compared with normal animals. This shows clearly the extent to which vision enters into the orientation of these animals.

c. Both Otocysts removed. The angle of compensation is here reduced to 3° and 5° , respectively, for the eyestalks on the side toward and from which the rotation takes place. Even without rotation the positions in which the eyes are held are not definite, as they are in animals which possess otocysts. The stalks often make an angle of 40° or more with the vertical, and their movements are no longer correlated. This, together with the marked decrease in the angle of compensation, as compared with that of blinded animals, makes it evident that in equilibration and orientation the otocyst plays a much more important part than does the organ of vision.

d. Both Eyes blinded and both Otocysts removed. On rotation it was found that the compensatory movements of the eyestalks were practically wanting. Two individuals only out of fifty showed movements of from 3° to 5° . In the greater number of cases no movement could be detected, and in the remainder the angle averaged less than 1° . There was a still greater tendency for the eyestalks to be held in indefinite positions when at rest, and at unequal angles. Fifteen such individuals were kept in an aquarium more than twenty days, and after this lapse of time practically the same results were obtained, showing that the shock of the operation of removing the otocyst had no effect upon the results of the experiments. Furthermore, removal of the antennules distal to the otocysts had absolutely no inhibiting effect upon the movements of the eyestalks.

This series of experiments corroborates, as far as they go, the conclusions of Clark ('96). It is clear from them that the otocyst is the chief organ in equilibration, though sight also plays an important part in the orientation of these animals.

Since the above work was done (July, 1899) a paper has been published by Lyon ('99) on the comparative physiology of compensatory movements. These movements were studied by him in many vertebrate and invertebrate forms; they were found to exist in insects as well as Crustacea. Using the crayfish, he confirms Clark's results to some extent, but finds that on blinding the animals and removing the otocysts a considerable angle of compensation still persists. This, together with the fact that insects, which lack otocysts, show the characteristic movements, he uses as an argument against the otocyst being an organ of equilibration. Lyon also finds that upon rotation about a vertical axis there is a

compensation movement of the eyestalks of the normal crayfish through an angle of 10° to 18° ; and, further, that when the animal is rotated about its long axis blinding causes a diminution of 10% in the angle of compensation. His results therefore give a much more important place to vision in orientation than do the conclusions of Clark and myself. However, from the combined results of the experiments of Clark, Lyon, and myself, one cannot avoid the conclusion that, in the fiddler crab at least, the otocyst is by far the most important organ in equilibration; next in order comes vision, and then muscular and tactile sense.

3. *Equilibration of Animals normally without Otocysts.*

Virbius zostericola, a shrimp quite common at Wood's Hole, Mass., does not possess otocysts. Observation and experiment brought out several interesting facts concerning it. In the first place, it is not a free-swimming form. Its normal habitat is on the eel grass, to which it clings in positions indifferent to the direction of gravity. When forced to swim, it does so in a very uncertain manner, with the dorsal side usually uppermost, though this is a position of unstable equilibrium. If overturned artificially (and this is easily accomplished), it rights itself slowly and will cling to the first object it may chance to touch. Removed from its supporting blades of eel-grass, its unstable manner of swimming closely resembles that of shrimps in which the otocysts have been destroyed. If the eyestalks are painted with lampblack, and the animals so treated are placed in a large aquarium, and forced to swim, apparently all sense of direction and means of orientation are lost.

4. *The Effect of the Development of the Otocyst on the Equilibration of Lobster Larvæ.*

As has been shown in the morphological part of this paper, there is no otocyst in the newly hatched larva of either Palæmonetes, the lobster, or the crab, nor is there a functional organ during the first three larval stages. It begins to invaginate only in the second larval stage, and it is merely a shallow cup-like depression in the third stage; not until the next moult do the sensory hairs and otoliths appear.

When we examine the conditions as to equilibration and manner of swimming in the different larval stages, we find that in the first larva the body is not definitely oriented while swimming. Newly hatched lobsters are very unstable in their movements, often swim or come to rest upon their backs or sides, and show a tendency to roll from side to side while swimming. The animal swims by means of the exopods of the

thoracic appendages; the abdominal segments are flexed ventrally, and the thoracic endopods, hanging down, steady the rolling motions somewhat. In the second stage the conditions are essentially the same.

In the third stage the larvæ are more stable, though the otocyst is still functionless. This greater stability is explained when the

FIGURE B.

Lateral view of lobster larva of the third stage, showing swimming position. Magnified 6 diameters.

swimming position of the body and appendages is observed (Fig. B). The thoracic appendages are now relatively large, as compared with the size of the body. They are allowed to hang down ventrally, and in conjunction with the curved condition of the abdominal segments, serve to lower the position of the centre of gravity in the whole animal, thus rendering its swimming position much more stable.

FIGURE C.

Lateral view of lobster larva of fourth stage, illustrating the change in swimming position due to the presence of a functional otocyst. Magnified 6 diameters.

Turning now to the fourth larval stage, we find the swimming position of the body entirely changed (Fig. C). The abdomen is no longer flexed and curved ventrally, but is held in approximately the same horizontal plane as the cephalothorax, while the thoracic appendages, instead of dragging downward through the water, are held up and forward in a line parallel with the long axis of the body. The great chelæ project in front like the arms of a person preparing to dive, the exopods

of the thoracic appendages have been lost, and the larvæ now swim swiftly by means of the abdominal swimmerets.

Although, from the position in which the body and appendages are held, the larva is in unstable equilibrium, it now orients itself very definitely during locomotion, in sharp contrast to the preceding stages. All signs of rolling from side to side, or pitching forwards, are completely lost. The larva swim straight ahead with the body held usually in a horizontal plane and dorsal side up. The same position is also invariably maintained when the animals come to rest.

Thus this sudden change as to form and swimming position in the fourth larva, unfavorable though it is for equilibration, is yet accompanied by more delicate powers of orientation, and greater stability in swimming than are met with in the three earlier stages, where the centre of gravity of the animal is lower. Bearing in mind the fact that the otocyst first becomes functional in the fourth larval stage, we can only conclude that an intimate connection exists between its appearance as an active organ, and the delicate static sense which is suddenly exhibited by the larvæ.

If larvæ of the first, second, and third stages are blinded, their powers of orientation are almost entirely lost, but the same experiment has little or no effect upon the equilibration of the fourth larva. The first three stages thus depend mainly on vision for their imperfect orientation; in the next stage this function has been largely transferred to the otocyst.

A similar correlation between the development of the otocyst and the appearance of a static sense is found in the metamorphosis of the crab. The pelagic unstable Zoea larva is without otocysts, while the Megalops larva, which exhibits perfect powers of equilibration, possesses these organs well developed, and even containing otoliths, which are absent in the sac of the adult.

The correlation which evidently exists between the formation of the functional otocyst and the sudden increase in static powers exhibited by lobster larvæ is particularly well shown in the marked alteration in the swimming position maintained by the fourth larva, as compared with that of the three earlier stages. Previous to the fourth stage, the lack of a delicate static organ is compensated for by the maintenance of an attitude in swimming which increases the stability of the moving body. Just as Bethe ('95) found that Mysis, deprived of its otocysts, would after an interval of some days recover its power of orientation by curving the abdomen upward and thus, by lowering the centre of gravity,

put the body in natural equilibrium, so in the case of the first three lobster larvæ, the attitude maintained is an adaptation for the greater stability of the free-swimming animal, as yet without static organs. But when, in the next stage, the otocyst becomes functional, such an adaptation is no longer necessary, and the sudden change to the unstable swimming position of the fourth larval stage results (Fig. *C*). This is the more natural attitude, and is advantageous to the animal in that it allows of greater speed in swimming.

5. *The Function of the Otoliths.*

At the time when the otocyst was regarded as an auditory organ, the otoliths were supposed to act simply as intensifiers of the sound vibrations, but viewing the sac as a static organ, the rôle played by the otoliths must assume a different aspect. The fact that they are wanting in the Brachyura, which nevertheless exhibit strong powers of orientation, might be used as an argument against their playing any important part in equilibration. But as they are present in the larval crab, and as they disappear only when the otocyst becomes highly differentiated, and when sensory hairs much more delicately constructed than the otolith bristles are developed, this argument loses most of its weight.

For determining the functions of the otoliths two methods may be employed: (*a*) Observing the effect on equilibration and orientation following the removal of the otoliths, or the prevention of the normal process of taking them in after ecdysis. (*b*) Substitution of iron dust or iron filings for the otoliths, and the employment of an electro-magnet to modify the action of gravity. If the otoliths are static in function, the animals should orient themselves with reference to the resultant of the attraction of the magnet, and the pull of gravity.

The first of these methods was attempted by Kreidl ('94), but failed, as he was unable completely to remove the otoliths. His results with the second method of experimentation were definite and affirmative. Lyon ('99) attempted to repeat and verify Kreidl's work, but his experiments were incomplete and negative in their results.

Otoliths, always normally present in macruran decapods, are lacking for only a short time after ecdysis. So short indeed is this interval, that it is extremely difficult to find otocysts of newly moulted animals which are without otoliths. Nor is it usually possible to prevent a crustacean which has been observed to cast its test, from getting new otoliths into the sac; at least not for a sufficiently long period to allow

the animal otherwise to regain its normal condition. Even if placed at once in filtered water, some otoliths soon make their appearance, probably originating from the excreta of the animals themselves.

In lobsters the larvæ regain their normal condition within a much shorter interval after ecdysis than do adult individuals; their digestive tract is also much less likely to contain material suitable for the formation of otoliths. Therefore, after trying in vain to completely remove the otoliths from the sacs of Crangon and Palæmonetes, my attention was directed to lobster larvæ as much more favorable material than the adult shrimps. As they moult at intervals of a few days, it is also much easier to obtain them directly after ecdysis or in the very act itself. So obtained, and placed at once into filtered sea water, larvæ of the fourth stage may be kept without otoliths for from twenty-four to forty-eight hours, and a favorable opportunity is thus given for observing the effect produced by the lack of otoliths on the equilibrium of the animals.

Observations were made on eighteen larvæ of the fourth and fifth stages, all of them being kept free from otoliths for at least twelve hours. Within two hours after moulting most of them swam about actively, and ate greedily when fed with bits of crab's liver. In swimming, however, they show distinctly the phenomena manifested by shrimps which have been deprived of their otocysts. There is both "rolling" from side to side, and "pitching" forward and backward; often they swim with the ventral side uppermost. Much more easily overturned than normal larvæ, they do not right themselves at once, but if turned upon the back, will continue to swim in that abnormal position. If blinded, the loss of equilibrium is still more marked. All these conditions are in strong contrast to the actions of the normal free-swimming larvæ of these stages, which conduct themselves in the characteristic manner already described for Palæmonetes.

The observations having been made and recorded, the animals were killed, and the otocysts dissected out and examined under the microscope. Scarcely a particle of inorganic matter was found in the sacs of sixteen larvæ. In two individuals a few small grains of sand were found in one otocyst, but the other was entirely destitute of otoliths.

From the number of cases observed it seems safe to conclude that the otoliths do play an important part in equilibration, and that it is the pull of gravity upon them which stimulates the sensory hairs of the sac. If the loss of the power of accurate orientation were to be attributed to the abnormal conditions resultant upon ecdysis, it might be said in

reply that the larvæ were perfectly normal when observed, as far as feeding and active swimming were concerned, and furthermore that the loss of equilibration disappeared at once when a larva without otoliths was allowed to obtain them. The results of these observations are also confirmed by the following experiments.

The otoliths were removed from the sacs of *Palæmonetes* by lifting the lid which covers the aperture, and forcing a fine jet of water into the cavity. Most of the sand having been thus washed out, the animals were placed in an aquarium upon the floor of which iron filings had been scattered and were allowed to remain until the iron particles had been taken into the sac in place of grains of sand. As an electromagnet, a steel bar 8 inches long and one quarter of an inch square was used. This was ground down nearly to a point at one end; about the other end were wound many layers of fine copper wire, the termini being connected with the circuit of a small six-celled battery. The shrimps employed in the experiments (*Palæmonetes*) were blinded by the usual method, — painting the eyestalks with a mixture of lampblack and shellac. The pointed end of the magnet was held about 3 cm. from the otocysts, at one side of and a little ventral to them. Animals with normal otoliths, if blinded, do not respond at all, and are apparently unaffected by the proximity of the magnet; they keep their normal position, dorsal side up, with the sagittal plane of the body coincident with the direction of gravity. If not blinded, they simply move slowly away from the magnet when it approaches too near. When, however, the magnet is brought into close proximity to otocysts containing iron filings, the dorsal side of the animal is turned, not toward the magnet, as might be expected if the changed position were due directly to the action of the magnet on the iron filings, but away from it. If the magnet was changed to a position on the other side of the shrimp, the turning was in the opposite direction, still away from the source of attraction.

The above reaction was distinctly noted a number of times for each of the six animals experimented upon. As Kreidl's work was fairly complete, only one series of experiments was tried in confirmation of his results. When the observations had been completed, the antennules of the six shrimps were removed and the otocysts examined under the microscope. In each case particles of iron were found nearly filling the sac, and if a magnet was held close to one of the latter, the whole antennule was lifted by the attractive force, showing clearly that there must have been an effective magnetic pull upon the otoliths of the live

animals during the experiments. I believe there is only one explanation for this turning of the body away from the attracting force, and that is a very simple one. Under normal conditions the body of the shrimp is oriented with reference to gravity, and its dorso-ventral axis approximately corresponds to the direction of this force. If the shrimp rotates around its chief axis either to right or left, say 90° , the direction of the pull of gravity on the otoliths is at once changed, and through the medium of the latter other sensory hairs of the sac are stimulated. As a result, the shrimp turns back in a direction opposite to that in which it was rotated, until it is again in a normal relation to the direction of gravity. The employment of the magnet has no other effect than merely to change the direction of the orienting force. This is now no longer that of gravity alone, but *the resultant* of the two component forces, gravity and the pull of the magnet. The animal now maintains its swimming position in reference to this new line of attraction, its dorso-ventral axis coincident with that line, and as a result the dorsal side is turned away from the magnet. To put it in another way, when the magnet is held close to the right side of the otocyst, the animal is stimulated precisely as it would be if rotated to the right 45° , and it responds as it would normally in righting itself, i. e., by turning its body in the opposite direction through an angle sufficient to make its dorso-ventral axis coincide with the direction of the attractive force; in this case through an angle of 45° .

This single series of observations completely confirm, as far as they go, the very important conclusions of Kreidl. The otoliths are found to play an important part in the functional activities of the otocyst, and the latter is conclusively proved to be a static organ, acted upon by the force of gravity; this force makes itself felt chiefly through the medium of the otoliths, and if they are absent, as described in a preceding set of experiments on lobster larvæ, the function of the otocyst in *Macrura* is seriously impaired.

6. *The Function of the Hairs of the Otocyst.*

The function of the otocyst hairs of macruran decapods which are in contact with otoliths has been already briefly discussed in the first part of this paper. The stimulus imparted to the hair shaft through the medium of the otoliths makes itself most strongly felt at the labile base of the hair, owing to the rigidity of the shaft and the delicacy of the attaching membrane. At this point, too, the nerve fibre invariably ends, and the stimulus is thus transmitted to it, and at once carried to the

brain. In the case of adult *Brachyura*, however, there are no otoliths in contact with the hairs of the otocyst, consequently the effect of gravity, if not entirely null, must be at least greatly lessened, unless indeed the hairs are so differentiated as to be themselves stimulated by it.

Bethe ('97), acting on the idea that in tilting the animal the difference in the pressure of the water might affect the hairs of the otocysts, placed crabs under very high pressures where the slight difference brought about by tilting would be practically eliminated. But he found that all the phenomena of equilibration still persisted.

It is probable that in the otocyst of *Carcinus* the thread hairs are the most important sensory organs of the sac. The hook hairs, originally in the larva attached to otoliths, later, with the loss of the sand granules, lose much of their functional activity; the third group of hairs cannot be of great importance, as I could not demonstrate satisfactorily their nerve connections, and their structure alone is such as to preclude their being affected by very delicate stimuli. The thread hairs, however, in both structure and position are fitted for the fulfillment of such a function as has been ascribed to them. The shaft is long, attenuate, only slightly fringed at the tip, and attached at the base by a very thin membrane, which allows free movement to the rigid shaft about this region as upon a joint. I have observed in studying freshly dissected otocysts that a slight tilting of the watch glass in which they were contained caused these hairs to sway extensively.

From Clark's experiments and my own, it was apparent that upon rotation in a horizontal plane, there was little or no compensatory movement of the eyestalks, and that when there is such a reaction, the angle of compensation is not maintained, but the eyes return at once to their original positions. Also, on rotation about the animal's lateral axis, the angle of compensation is not as great, when the rotation is rapid and jerky, as when performed slowly and smoothly. These two facts preclude the possibility of the hairs being affected by movements of the fluid surrounding them, at least to any great extent. For if they were so affected, the angle of compensation should be the same, in whatever plane the animals are rotated, and the position of the eyestalks should be in every case maintained by compensation movements.

There still remain two ways in which the hairs may be so affected as to bring about nervous stimulus. Either they may be lighter than the surrounding fluid, and consequently tend always to float erect, no matter what position the otocyst may take relative to them; or they may be

heavier than the liquid contents of the otocyst, in which case they would be affected by gravity directly, and exposed to a greater or less pull according to their different positions in the sac. My observations made on dissections of fresh material of both young and adult crabs, do not confirm the first of these hypotheses. The hairs rarely, if ever, float upright in the fluid of the otocyst; on the contrary they usually project out horizontally, with their tips a little lower than their bases; and such conditions would favor the second supposition, that they are heavier than the surrounding fluid. Unfortunately, when fresh material was at hand, my attention was directed toward other problems, and no dissections or observations were made with the settlement of this question primarily in view. It is, however, a point well worth future experimentation, for the function of these hairs is apparently similar to that of the auditory hairs of the vertebrate cristæ acusticæ, and to clearly show how they are stimulated would throw light on an important problem in the physiology of the vertebrate ear.

SUMMARY.

1. The cuticular lining of the otocyst, found in the basal segment of the antennule of all decapod Crustacea, is cast with the test at each moult. It is composed of thin chitin, and is suspended from the dorsal wall of the antennule, which presents an aperture in *Macrura*, in the larval stages of *Brachyura*, and also in adult *Brachyura* directly after ecdysis.

2. In *Macrura* a single sensory prominence is present, either on the floor or sides of the sac. In *Brachyura* there are three sensory regions. The sensory hairs are borne upon these cushions, usually in curved rows.

3. The otolith hairs are heavily fringed, often bent or hooked. In *Macrura* they are attached to the wall of the sac by a thin bulb of chitin; in *Brachyura* the base of the hair shaft is inserted into a cup-like depression; both methods of attachment allow the hair to sway freely upon its base.

4. The free hairs of the otocyst, found in the lobster and all *Brachyura*, are extremely long and attenuate; their basal attachment is delicate, and renders them much more sensitive than the otolith hairs.

5. All sensory hairs are formed as double-walled tubes by numerous matrix cells situated beneath the hypodermis, from which they originate. After ecdysis processes from these cells extend into the shaft of the newly formed hair. In preparation for the next moult these processes

are withdrawn, the matrix cells recede from the base of the old hair, and arrange themselves about the nerve fibre for the formation of the new bristle. There is a period between moults, more or less extended, during which no living substance is present in the greater part of the cavity of the hair.

6. The otoliths are grains of sand taken in from the exterior (first, in the case of the lobster, by the fourth larva) and renewed after each moult; they may lie free in the otocyst, or be attached to the sensory hairs. In *Brachyura* they are found only in the *Megalops* stage.

7. Glands similar in structure to the tegumentary glands are present in the lobster and crayfish beneath the sensory cushions which bear otolith hairs. They secrete a substance for the attachment of the otoliths to the pinnules of the bristles.

8. The innervation of the otocyst hairs and olfactory bristles is distinctly unlike.

(a) The otocyst hairs have each a single nerve element, and the terminal fibre ends in the enlarged base of the shaft without branching.

(b) Each olfactory bristle is innervated by numerous ganglion cells (100 or more). The peripheral strand of fibres from these cells extends some distance into the cavity of the hair, terminating free and without modification of any kind.

9. The central terminations of all the otocyst fibres are in two closely connected neuropilar masses at the posterior end of the brain, median to those of the second antennæ, and ventral to the optic centres. The nerve sheaths disappear as the fibres enter the "Punksubstanz," and the fibrillæ soon separate. They cannot be traced to determinate endings, nor are they ever directly connected centrally, with ganglion cells.

10. Each sensory nerve fibre is composed of numerous fibrillæ, embedded in a semi-fluid "perifibrillar" substance, which in turn is surrounded by a delicate sheath. The flowing together of the perifibrillar matrix causes the beaded or varicose appearances characteristic of methylen blue, and silver impregnations. The fibrillar structure can be demonstrated in both the central and peripheral portions of the fibres.

11. The sensory ganglion cells are all typically bipolar and elongate in form. They are placed at some distance from the base of the hair which they supply, and show no fibrillar structure.

12. In the shrimp-like decapods, such as *Palæmonetes* and *Crangon*, a nucleated myelin sheath surrounds each sensory fibre and ganglion

cell, extending from the neuropil of the brain nearly to the peripheral ending of the fibre.

13. Each sensory ganglion cell with its central and peripheral fibres constitutes a single nervous element or neuron. The neurons are trophic units, and direct connection between two neurons was not demonstrated.

14. In those decapods which pass through free-swimming larval stages, the otocyst develops as an invagination of the dorsal ectoderm of the basal segment of the antennule, and becomes functional only at the fourth moult after hatching.

15. Invagination begins at the second larval stage, but the matrix cells which are to form the sensory hairs of the sac, make their appearance in the first larva, being derived from the cells of the hypodermis.

16. During the third stage the sensory hairs are formed below the floor of the shallow sac; at the next moult these become functional, the sac enlarges, and otoliths make their appearance. The otocyst is now functional, the hairs are innervated as in the adult, and more than 100 of them may be present. After the fourth stage the chief changes are the increase in the number of otocyst hairs, and the gradual constriction of the orifice of the sac.

17. In Brachyura the Zoea larva is without a functional sac. In the Megalops the otocyst is open, and contains numerous sensory hairs and otoliths. During the next two stages the aperture closes and takes on the adult condition, without otoliths.

18. Structurally, the otocyst of decapods may be compared roughly to the utricle of such a vertebrate as *Myxine*; the sac of *Palæmonetes* to a single isolated ampulla, and its sensory cushion to a crista acustica. The closed otocyst of Brachyura has three sensory regions and is without otoliths. It therefore approaches in general structure the utricle of the higher vertebrates. Each sensory element of the otocyst is comparable to a single sensory component in the vertebrate crista. In each there is a modified organ for the reception of stimuli, connected basally with the terminal fibre of a sensory neuron.

19. There is no part of the decapod otocyst which is structurally comparable to the middle ear, semi-circular canals, or cochlea of vertebrates.

20. There is no direct evidence to prove that decapod Crustacea react to true sounds produced either in water or in air. The reactions formerly attributed to audition are probably due to tactile reflexes.

21. The otocyst plays little or no part in calling forth these reactions, and does not function as a true auditory organ.

22. Equilibration is made possible by three sets of organs, the otocysts, the eyes, and the tactile bristles.

23. In free-swimming decapods the otocyst is by far the most important of these static organs functionally, vision being secondary to it. Four facts go to prove this:

(a) The removal of the otocysts causes a much greater loss of power of orientation, and a greater decrease in the compensatory movements of the eyestalks, than the loss of vision.

(b) Decapods and Entomostraca normally without otocysts either swim in unstable equilibrium, or in a position identical to that which an inanimate object of the same form and weight would take under the influence of gravity.

(c) Lobster larvæ without functional otocysts are unstable in their swimming movements, but orient themselves with great accuracy at the stage when the sac becomes an active sense organ.

(d) If iron filings are substituted for the otoliths, and an electromagnet is employed to modify the effect of the pull and direction of gravity, shrimps orient themselves with reference to the direction of the resultant pull of the two forces, precisely as they do to the attraction of gravity alone.

24. In lobster larvæ of the third and fourth stages there is a direct correlation between the metamorphosis of the otocyst from a functionless to an active organ, and the changes in the swimming position of the animal. When the sac is inactive (third stage), the swimming position of the body and appendages is an adaptation which places the larvæ in comparatively stable equilibrium. As the otocyst becomes functional (fourth stage), this adaptation is no longer necessary, and a much less stable position is maintained, but one more favorable for rapid locomotion.

25. The otoliths in *Macrura* and larval *Brachyura* are the means by which the pull of gravity is transmitted to the hairs of the otocyst. On their complete removal there is loss of equilibration and power of orientation; if iron filings are substituted for them, shrimps may be made to respond to the attraction of an electromagnet.

26. In adult *Brachyura* otoliths are normally lacking. The otolith hairs have become practically functionless, and the thread hairs are modified in such a way as to make them directly responsive to the attraction of gravity without the aid of the otoliths.

EXPLANATION OF THE PLATES.

All Figures were outlined with an Abbé camera lucida. Tube length was usually 160 mm., with projection distance to the table, 410 mm. The magnifications are given with the descriptions of the several figures. Drawings were made from sections, unless the contrary is stated. The orientation of the figures is given for each plate.

ABBREVIATIONS.

<i>cl. gl.</i> . . .	Gland cell.	<i>nl. tu.</i> . . .	Sheath nucleus.
<i>cl. gn.</i> . . .	Ganglion cell.	<i>n. opt.</i> . . .	Optic nerve.
<i>cl. mat.</i> . . .	Matrix cell.	<i>n. ot.</i> . . .	Otic nerve.
<i>co'nt. cre'oes.</i>	Circumœsophageal connective.	<i>n'pil. at.1</i> . . .	Neuropil of antennule.
<i>crs. sns.</i> . . .	Sensory crista.	<i>n'pil. at.2</i> . . .	Neuropil of antenna.
<i>cta.</i> . . .	Cuticula.	<i>n'pil. opt.</i> . . .	Optic neuropil.
<i>cta'.</i> . . .	New cuticula.	<i>n. teg.</i> . . .	Tegumentary nerve.
<i>dt.</i> . . .	Duct.	<i>of.</i> . . .	Orifice.
<i>fbr'.</i> . . .	Fibrillations.	<i>ot'cy.</i> . . .	Otocyst.
<i>fbr. ass.</i> . . .	Association nerve fibre.	<i>ot'lt.</i> . . .	Otoliths.
<i>fbr. c.</i> . . .	Central nerve fibre.	<i>pinn.</i> . . .	Pinnules of hairs.
<i>fbr. n.</i> . . .	Nerve fibre.	<i>pr'c. pr'pl.</i> . . .	Protoplasmic process.
<i>fbr. pi'ph.</i> . . .	Peripheral nerve fibre.	<i>rm. l.</i> . . .	Lateral branch of antennular nerve.
<i>fl.</i> . . .	Flagellum.	<i>ro.</i> . . .	Rostrum.
<i>glb.</i> . . .	Globulus.	<i>set.'</i> . . .	Group hairs.
<i>gn. olf.</i> . . .	Olfactory ganglion.	<i>set. jil.</i> . . .	Thread hairs.
<i>h'drm.</i> . . .	Hypodermis.	<i>set. l.</i> . . .	Laterai hairs.
<i>lab. a.</i> . . .	Anterior lip of orifice to otocyst.	<i>set. m.</i> . . .	Median hairs.
<i>lab. p.</i> . . .	Posterior lip of same.	<i>set. olf.</i> . . .	Olfactory hairs.
<i>lu.</i> . . .	Lumen of otocyst.	<i>set. ot.</i> . . .	Otic hairs.
<i>mal.</i> . . .	Hammer.	<i>set. p.</i> . . .	Posterior hairs.
<i>mb. sph.</i> . . .	Spherical membrane.	<i>set. ta.</i> . . .	Hook hairs.
<i>n. at.1</i> . . .	Antennular nerve.	<i>set. tac.</i> . . .	Tactile hairs.
<i>n. at.2</i> . . .	Nerve of 2d antenna.	<i>tb. set.</i> . . .	Hair tube.
<i>n'bl.</i> . . .	Neuroblasts.	<i>tct.</i> . . .	Tectum of otocyst.
<i>n'lem</i> . . .	Neurilemma.	<i>tu. myl.</i> . . .	Myelin sheath.

PLATE 1.

All Figures are of *Palæmonetes*. In Figure 1 anterior is up on the plate; in Figures 2, 3, and 4 the dorsal side is up, and the anterior end in Figure 4 is at the left. Lines numbered 2, 3, 4, 5 in Figure 1 indicate the planes of the sections shown in Figures 2, 3, 4, and 5 respectively.

- Fig. 1. Dorsal view of the basal segment of both antennules, showing otocysts and the arrangement of the hairs in the sac. $\times 30$.
- Fig. 2. Somewhat oblique transverse section, extending from dorsal anterior to ventral posterior, of both antennules and the rostrum, through the posterior ends of the otocysts (compare line 2, Fig. 1). $\times 64$.
- Fig. 3. Transverse section of right antennule through the orifice of the sac, showing tectum and otoliths (compare line 3, Fig. 1). $\times 64$.
- Fig. 4. Parasagittal section through right antennule and brain, showing the course of the otic nerve, with a single nerve element drawn diagrammatically (see line 4, Fig. 1). $\times 64$.

PLATE 2.

All Figures are of *Palæmonetes*. The dorsal side is up in Figure 5, and the anterior end at the right.

Fig. 5. Parasagittal section through the lateral side of the right otocyst (see line 5, Fig. 1). $\times 64$.

Fig. 6. Transverse section through the posterior end of the sensory cushion, showing two lateral hairs, the base of a median one and a group of ganglion cells. $\times 168$

Fig. 7. Otocyst hair and matrix cells. $\times 600$.

Fig. 7a. Another otocyst hair and matrix cells. $\times 600$.

Fig. 8. Sensory hair of the otocyst and the ending of its peripheral nerve fibre. $\times 600$.

Fig. 9. Fundament of developing sensory hair from an abdominal exopod, showing matrix cells about the nerve fibre. Methylen-blue preparation. $\times 600$.

PLATE 3.

All Figures are from methylen-blue preparations of *Palæmonetes*. Anterior is up on plate in Figure 12.

Fig. 10. Part of abdominal exopod showing tubes of developing tactile hairs and their innervation. $\times 125$.

Fig. 11. Peripheral nerve endings in the tactile hairs of the second maxilliped. $\times 95$.

Fig. 12. Dorsal view of antennules and brain, showing sensory neurons and central endings of the otocyst nerve fibres. The peripheral endings in the left otocyst are diagrammatic. $\times 30$.

10

11

PLATE 4.

Figures 13-18 are of *Palæmonetes*. Figures 19-22 are of lobster larvæ. In Figures 19-21 dorsal side is up and the lateral side is at the right; in Figure 22 anterior is at the right, dorsal side up.

- Fig. 13. Portion of inner flagellum of first antenna, showing olfactory hairs and their peripheral ganglionic masses. Methylen blue. $\times 125$.
- Fig. 14. Gustatory hairs and nerve elements from the basipod of second maxilla. Methylen blue. $\times 95$.
- Fig. 15. Fibrillations in peripheral otic nerve fibre. Methylen blue. $\times 1300$.
- Fig. 16. Ganglion cell of otocyst and peripheral nerve process surrounded by myelin sheath. $\times 600$.
- Fig. 17. Ganglion cell of otocyst, and sheath nucleus. $\times 1300$.
- Fig. 18. Ganglion cell of otocyst. Methylen blue. $\times 770$.
- Fig. 19. Transverse section through right antennule of first lobster larva. $\times 168$.
- Fig. 20. Transverse section through right antennule of second lobster larva; beginning of invagination. $\times 168$.
- Fig. 21. Transverse section through right antennule of third lobster larva. $\times 168$.
- Fig. 22. Parasagittal section through antennule of second lobster larva. $\times 168$.

PLATE 5.

All Figures are of *lobster larvæ*. In Figures 23 and 25 dorsal is up, and anterior at the right; in Figure 24 dorsal is up and lateral is at the right; anterior is at the right in Figure 26.

Fig. 23. Parasagittal section through the antennule of the third larva. $\times 168$.

Fig. 24. Transverse section through the posterior part of the right otocyst in fourth larva. $\times 168$.

Fig. 25. Parasagittal section of the same. $\times 125$.

Fig. 26. Diagrammatic dorsal view of floor of right sac dissected out to show arrangement of the hairs and their innervation. Methylen blue. $\times 168$.

Fig. 27. Developing hairs of the otocyst in the third larval stage. $\times 600$.

PLATE 6.

Crangon ; in Figure 28 dorsal is up ; in Figure 29 anterior is up.

- Fig. 28. Transverse section of both antennules through the sensory cushions of the otocysts. $\times 95$.
- Fig. 29. Reconstruction from ten frontal sections through the base of both antennules and the brain. A semi-diagrammatic nerve element is shown at the left in black. $\times 95$.

28

n. at.

29

PLATE 7.

Figures 30 and 31 are of *Crangon*. All others are of *Cambarus*. In Figure 30 dorsal is up and lateral is at the left; in Figure 36 dorsal is up and lateral is at the right.

- Fig. 30. Parasagittal section of antennule and brain. $\times 95$.
Fig. 31. Otocyst hair. $\times 600$.
Fig. 32. Olfactory hairs from basipod of second maxilla, showing innervation. Methylen blue. $\times 95$.
Fig. 33. Posterior row of otocyst hairs and their nerve elements. Methylen blue. $\times 95$.
Fig. 34. Tactile hair from scaphognathite of second maxilla, showing innervation. Methylen blue. $\times 95$.
Fig. 35. Transverse section through shaft of otocyst hair. $\times 770$.
Fig. 36. Diagrammatic transverse section of the right antennule through the posterior part of the otocyst. $\times 15$.

PLATE 8.

All Figures are of *Cambarus*. Dorsal side is up in Figures 37 and 38; in Figure 38 anterior is at the left; anterior is up in Figure 40.

- Fig. 37. Transverse section through the orifice of both otocysts; left antennule is diagrammatic. $\times 25$.
Fig. 38. Parasagittal section through right antennule and brain. $\times 25$.
Fig. 39. Tegumentary gland from the sensory cushion of the otocyst. $\times 600$.
Fig. 40. Dorsal view of the sensory cushion of the left otocyst dissected out, showing the arrangement and innervation of the hairs. Methylene blue. $\times 62$.

PLATE 9.

Figure 41 is of *Cambarus*; all others are of *Carcinus*. In Figures 41 and 46 anterior is up; in Figures 42-45 dorsal is up and anterior at the left; in Figures 47 and 48 dorsal is up and lateral is at the right.

Fig. 41. Ventral view of brain, showing central endings of otic and antennular nerves. Methylen blue. $\times 30$.

Figs. 42-45. Outlines of four parasagittal sections through the left otocyst of *Carcinus*, cut along the lines of section marked with corresponding numbers in Figure 46. Figure 45 is most median, Figure 42 most lateral in position. $\times 15$.

Fig. 46. Dorsal view of both antennules. Numbered lines (42-48) indicate planes of section of corresponding Figures. $\times 8$.

Fig. 47. Transverse section through the orifice of right otocyst (see Fig. 46, line 47). $\times 15$.

Fig. 48. Transverse section through anterior end of the otocyst (see Fig. 46, line 48). $\times 15$.

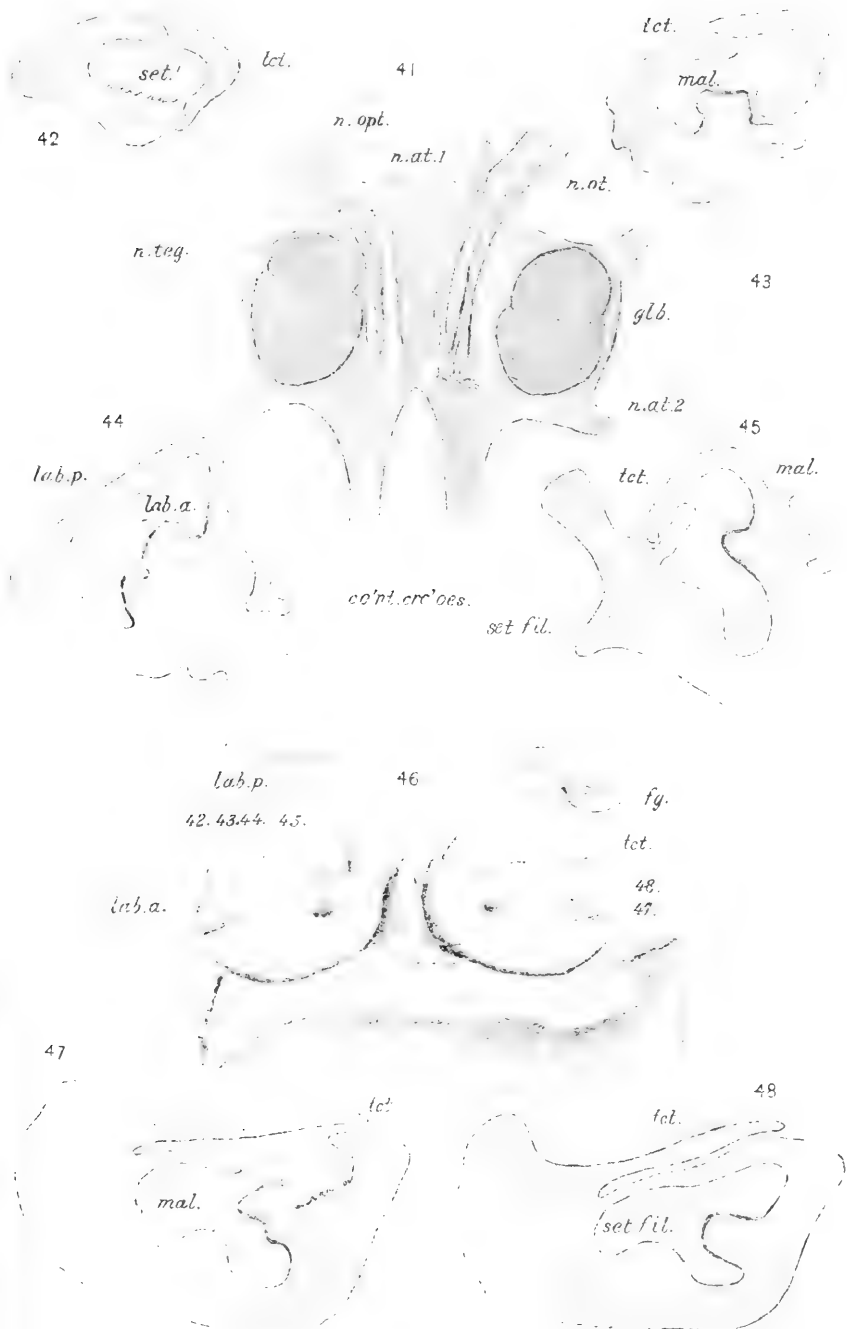

PLATE 10.

· All Figures are of *Carcinus* ; anterior is up in Figure 55.

- Fig. 49. Group hair. $\times 600$.
Fig. 50. Transverse section through the sensory cushion of the hook hairs.
 $\times 168$.
Fig. 51. Hook hair. $\times 600$.
Fig. 52. Portion of outer flagellum of antennule, showing the bases of olfactory hairs and their innervation. $\times 95$.
Fig. 53. Thread hairs and their nerve elements. Methylen blue. $\times 95$.
Fig. 54. Tip of thread hair. $\times 1300$.
Fig. 55. Nearly frontal section, inclining dorsal and forward, through both antennules and brain. $\times 25$.

The following Publications of the Museum of Comparative Zoölogy
are in preparation:—

Reports on the Results of Dredging Operations in 1877, 1878, 1879, and 1880, in charge of ALEX-
ANDER AGASSIZ, by the U. S. Coast Survey Steamer "Blake," as follows:—

- E. EHLERS. The Annelids of the "Blake."
- C. HARTLAUB. The Comatulæ of the "Blake," with 15 Plates.
- H. LUDWIG. The Genus *Pentacrinus*.
- A. MILNE EDWARDS and E. L. BOUVIER. The Crustacea of the "Blake."
- A. E. VERRILL. The Alcyonaria of the "Blake."

Reports on the Scientific Results of the Expedition to the Tropical Pacific, in charge of
ALEXANDER AGASSIZ, on the U. S. Fish Commission Steamer "Albatross," from August,
1899, to March, 1900, Commander Jefferson F. Moser, U. S. N., Commanding.

Illustrations of North American MARINE INVERTEBRATES, from Drawings by BURK-
HARDT, SONREL, and A. AGASSIZ, prepared under the direction of L. AGASSIZ.

LOUIS CABOT. Immature State of the Odonata, Part IV.

E. L. MARK. Studies on *Lepidosteus*, continued.

" On *Arachnactis*.

PUBLICATIONS
OF THE
MUSEUM OF COMPARATIVE ZOÖLOGY
AT HARVARD COLLEGE.

There have been published of the BULLETINS Vols. I. to XXXV.; of the Memoirs, Vols. I. to XXIV.

Vols. XXXVI., XXXVII., and XXXVIII. of the BULLETIN, and Vols. XXV., XXVI., and XXVII. of the MEMOIRS, are now in course of publication.

The BULLETIN and MEMOIRS are devoted to the publication of original work by the Professors and Assistants of the Museum, of investigations carried on by students and others in the different Laboratories of Natural History, and of work by specialists based upon the Museum Collections and Explorations.

The following publications are in preparation:—

Reports on the Results of Dredging Operations from 1877 to 1880, in charge of Alexander Agassiz, by the U. S. Coast Survey Steamer "Blake," Lieut. Commander C. D. Sigsbee, U. S. N., and Commander J. R. Bartlett, U. S. N., Commanding.

Reports on the Results of the Expedition of 1891 of the U. S. Fish Commission Steamer "Albatross," Lieut. Commander Z. L. Tanner, U. S. N., Commanding, in charge of Alexander Agassiz.

Reports on the Scientific Results of the Expedition to the Tropical Pacific, in charge of Alexander Agassiz, on the U. S. Fish Commission Steamer "Albatross," from August, 1899, to March, 1900, Commander Jefferson F. Moser, U. S. N., Commanding.

Contributions from the Zoölogical Laboratory, Professor E. L. Mark, Director.

Contributions from the Geological Laboratory, in charge of Professor N. S. Shaler.

These publications are issued in numbers at irregular intervals; one volume of the Bulletin (8vo) and half a volume of the Memoirs (4to) usually appear annually. Each number of the Bulletin and of the Memoirs is also sold separately. A price list of the publications of the Museum will be sent on application to the Librarian of the Museum of Comparative Zoölogy, Cambridge, Mass.

PRINTED FOR THE MUSEUM.
JULY, 1901.

No. 8. — *On a Collection of Birds from the Liu Kiu Islands.*
By OUTRAM BANGS.

THE Museum has recently acquired from Mr. Alan Owston of Yokohama an interesting collection of birds from the Yayeyama, or southern group of the Liu Kiu Islands. Though consisting of but one hundred and seven specimens, comprising fifty-six species, it contains six forms apparently hitherto undescribed. The collection was made by Mr. Ishida Zensaku and assistants from February to July, 1899, mostly in the Island of Ishigaki; some of the species were taken in the islands of Taketomi, Kobama, Hamarlijima, Kuroshima, Hatojima, and Iruduroto. The systematic sequence adopted is that of Stejneger in his Catalogue of Birds hitherto recorded from the Liu Kiu Islands.¹ I am indebted to the Museum authorities for placing the collection at my disposal for study, and am under special obligation to Dr. Leonhard Stejneger of the United States National Museum. Dr. Stejneger has made extensive studies of the fauna of the Liu Kiu Islands, and his aid and advice in comparing the specimens of the present collection with those in the National Museum have been of great value. I am also indebted to Mr. E. W. Nelson of the Biological Survey for comparing the noddy and sooty terns with those in the Department of Agriculture collection. In the following descriptions all measurements are in millimetres; the wing is measured in its natural curve, and not flattened down on the rule; the tail is measured by thrusting one point of the dividers to the base of the tail feathers and measuring thence to the tip of the longest rectrix. All colors, when definitely expressed, are according to Ridgway.²

Sterna melanauchen TEMM.

Two specimens, adult ♂ and adult ♀, from a small island near Taketomi, were taken June 20. [Eggs were collected from June 25 to July 5; a single egg laid on the ground.]³

¹ Proc. U. S. Nat. Mus., 1887, Vol. X. pp. 414-415.

² Ridgway, R. A Nomenclature of Colors for Naturalists, etc. Boston, 1886.

³ A list of the Zensaku collection, containing many notes on the distribution, nesting habits, etc., of the species taken, was published by Mr. Alan Owston (Yokohama, 1899). In this paper extracts from Owston's list are in brackets.

Sterna dougalli gracilis (GOULD).

Two specimens, an adult ♂ and an adult ♀, taken June 7 on a small island near Ishigaki. [Eggs were collected from June 19 to July 5.] These specimens are extreme of the slender-billed small form to which Gould's name *gracilis* applies. Specimens from western Europe and Africa agree closely in measurements with those from eastern North America and the West Indies. The red bill claimed as a character of *gracilis* may be due to age, many young specimens from America having red bills, while in the adult birds it is black. The differences between the two races of the Roseate Tern in size and in measurements of the bill are well marked.

The Liu Kiu Islands specimens agree in measurements with the Australian form, upon which Gould based his *S. gracilis*, and there can be no doubt of their identity.

The measurements of the two specimens are as follows:—

No.	Sex.	Wing.	Tail. ¹	Tarsus.	Exposed Culmen.
37,304	♂	221	110	20.2	36.6
37,305	♀	216	109	19.4	36.

Sterna fuliginosa crissalis (BAIRD).

Two specimens from a small island near Iriomote, adult ♂ and adult ♀, taken June 10. [Eggs, one in a clutch, laid on the rock, were taken June 1.]

Sterna bergii boreotis,² subsp. nov.

TYPE. — Mus. Comp. Zoöl., No. 37,301.

A single adult ♂ in full breeding plumage from Ishigaki, June 15, 1899. [Said to breed on Ishigaki.]

Subspecific Characters. — As small as the pale gray *Sterna bergii poliocerca* of Tasmania and South Australia; differing from it in having the wings, tail, and mantle very dark smoke gray, almost mouse gray.

Color. — Type, adult ♂ in full plumage. Forehead, cheeks, lores, ear-coverts, neck all round, and whole under parts, including lining of wing and bend of wing, pure white; crown and long occipital crest glossy black; mantle, wings, rump, upper tail coverts, and upper surface of middle rectrices dark smoke gray, darkest on wings and middle of back, where the color is almost mouse gray; primary quills white; 1st primary with outer web, a band along quill on inner web and tip blackish, with a silvery suffusion which is most marked toward centre of feather; broad outer margin of inner web, below the black tip

¹ The tails are measured to the end of the second rectrix, the streamer varying too much in length individually to be taken into account.

² Boreotis, northern.

white; 2nd primary similar but black tip deeper in color and extending a short distance down outer margin of inner web, thus enclosing the white of inner web for a short distance; 3rd, 4th, and 5th primaries like 2nd, but black tip gradually growing deeper in color; outer rectrices above pale smoke gray at tips and along shafts, pale grayish white toward base; 2nd and 3rd rectrices darker on the outer webs and at tip and whitish toward base of inner webs; bill, in dried specimen, dull yellow clouded with olive toward base; feet and tarsi blackish.

*Measurements.*¹—Adult ♂, type, wing 344; tail 178; tarsus 28; culmen 62.

Remarks.—*Sterna bergii* was first recorded from this region (breeding on small islands off the north coast of Formosa) by Swinhoe (Ibis, Vol. II. p. 68, 1860); since then two specimens have been noted by Stejneger, both from the Yayeyama Islands, the first in Proc. U. S. Nat. Mus., 1887, Vol. X. p. 392; the second in Vol. XIV. p. 490, 1891. But the question Stejneger raised in 1887, "Will anybody kindly inform me what name properly belongs to the smaller dark birds from the China seas?" has hitherto remained unanswered. My type of *Sterna bergii boreotis* agrees with the descriptions of Stejneger's specimens, and I propose for the small dark northern form of Bergius's tern the trinomial given above. When Saunders wrote his account of Bergius's tern, he had a large series of specimens at his command. He devotes but a few lines to the exceedingly interesting geographical variations of this wide-spread species, and after pointing out, in rather a vague way, how well marked the various races are, ends by including them all under one name.

The principal races of *Sterna bergii* may be indicated as follows:—

1. *Sterna bergii bergii* Licht., South Africa, large, gray of upper parts pale.
2. *S. bergii velox* (Cretzschm), Red and Arabian Seas and Bay of Bengal, large, gray of upper parts very dark.
3. *S. bergii pelecyanoides* (King), northern parts of Australia, intermediate between the last two in size and coloration.
4. *S. bergii poliocerca*¹ (Gould), Tasmania and South Australia, small, gray of upper parts pale.
5. *S. bergii boreotis*, subsp. nov., Liu Kiu Islands and Northern China Sea, small, gray of upper parts very dark.

Still another race that may prove distinct is the Polynesian *S. rectirostris* Peale, described from the Fiji Islands.

¹ Three specimens of *S. bergii poliocerca* in the Mus. Comp. Zool. afford the following measurements:—

No.	Sex.	Locality.	Wing.	Tail.	Tarsus.	Culmen.
8,781	♂	Australia.	334	158	31	59.5
12,018	♀ (?)	Melbourne, Aust.	332	173	27	56.
8,782	♂ (?)	Australia.	340	146	30	59.

For further measurements, see Stejneger, Proc. U. S. Nat. Mus., 1887, Vol. X. pp. 393-394.

Anous pullus,¹ sp. nov.

TYPE. — Mus. Comp. Zool., No. 37,298.

Two specimens, an adult ♂ and an adult ♀, from a small rocky island near Iriomote, June 10. [Eggs, one in a clutch, laid on the bare rock, were taken July 1.]

Characters. — A large very dark brown noddy with a gray crown, nearest to *A. rousseaui* Hartl. of Madagascar and adjacent islands, from which it differs by being much darker in color and slightly smaller in size.

Color. — Adults, in unworn, full breeding plumage. Narrow superciliary streak, ending above eye, lower eyelid, and a spot on upper eyelid whitish; forehead pearl gray, this color extending over crown and gradually darkening to slate gray on occiput, and thence merging on hind neck into the brown of upper parts; lores and region above the eye below the whitish streak black; upper parts rich dark chocolate brown, with a slight grayish cast; primaries and rectrices dark blackish brown; chin and sides of head blackish slate; rest of under parts deep chocolate brown; lining of wing brownish slate; bill, in dried specimens, black; feet and toes reddish brown.

Measurements: —

No.	Sex.		Wing.	Tail.	Tarsus.	Culmen.
37,297	♂	Topotype.	273	164.5	25.	39.
37,298	♀	Type.	271	159.5	24.5	38.

Remarks. — A comparison of the two specimens upon which I base this new noddy with the material in the National Museum and the Museum of Comparative Zoölogy shows them to be much nearer to *A. rousseaui* than to any of the other forms. The comparison was made with skins of *A. rousseaui* from the Seychelles and Mauritius. The Liu Kiu birds are much darker in color throughout, especially so about chin, sides of neck, and breast, and they are also smaller, the wing of the Mauritius specimen being 285 mm. long, and I have no hesitation in proposing a name for the Liu Kiu noddy.

Compared with other noddies, the differences are still greater; thus the Liu Kiu form is much darker than *A. ridgwayi* Anthony from Socorro and Tres Marias, especially about sides of head and throat, and the crown is darker and grayer.

From *A. galapagensis* Sharpe the new species differs in not having so black a body or such a dark gray crown.

From the noddy of eastern America — true *A. stolidus* — the Liu Kiu bird is very distinct, and can at once be told by its larger size and gray crown and forehead, the forehead and most of the crown in *A. stolidus* being white or yellowish white.

A. pullus differs much from the small slender-billed species, *A. leucocapillus*, *A. hawaiiensis*, and *A. tenuirostris*, in being larger and having a stouter bill.

¹ Pullus, dark-colored, dusky.

Puffinus leucomelas TEMM.

Two specimens from a small island near Iriomote, taken June 7. [One egg was taken July 1, from a hole in the rock about six feet deep.]

Bulweria bulweri (JARD. & SELB.).

One adult ♀ from Hanarejima, June 25. [Two eggs supposed to belong to this species were taken on the same island, June 20.]

Arenaria interpres (LINN.).

One adult ♂ in full plumage, Ishigaki, May 10.

Charadrius dominicus fulvus (GMEL.).

Two females from Ishigaki, March 1 and June 1.

Aegialitis alexandrina (LINN.).

One specimen, March 13, Ishigaki. [Eggs were collected, April 29 to June 20.]

Ochthodromus mongolus (PALL.).

One ♀ from Ishigaki, June 1.

Actitis hypoleucos (LINN.).

One ♀ from Ishigaki, March 12.

Heteractitis brevipes (VIEILL.).

One ♀ in winter plumage, Ishigaki, March 12.

Gallinago gallinago (LINN.).

One ♀ from Ishigaki, March 25.

Limnobæus phæopygus (STEJN.).

Three specimens from Ishigaki, adult ♂ taken May 1, adult ♀ June 20, and a chick June 19. The chick is covered with black down, which on the back is shining blue black, the bill and a patch of bare skin below the eye are yellow.

The wing in the adult ♂ is 105.4, in the adult ♀ 104. Neither of these has white spots on the outer web of 1st primary, such as Stejneger describes. [Nests containing six eggs each were found among reeds from April 10 to July 4.]

Rallina sepiaria (STEJN.).

Two adults from Ishigaki, ♂ taken March 20 (wing 146), ♀ taken April 2 (wing 150).

Gallinula chloropus orientalis (HORSE.).

Two adults, ♂ and ♀, from Ishigaki, taken March 21.

Fuligula fuligula (LINN.).

Two adults from Ishigaki, ♀ taken May 20, ♂ June 13. The male lacks the white spots on the chin.

Anas zonorhyncha SWINH.

Two adults from Ishigaki, ♂ May 10, ♀ June 1. [Many nests were found placed on the ground among grass, and eggs, seven in a clutch, taken from April 19 to June 25.]

Nettion crecca (LINN.).

One female from Ishigaki, March 7.

*Dendrocygna*¹ *javanica* (HORSE.).

Two adults from Ishigaki, ♂ taken May 25, ♀ June 1. [Nests were found on the ground among tall grass, and eggs, six in a clutch, taken from May 31 to June 21.]

Sula sula (LINN.).

Two specimens, adult ♂ from Iriomote, June 20, adult ♀ from Ishigaki, June 15. [Eggs were found two in a clutch, on outlying rocks, May 12 to June 13.]

Gorsachius melanolophus (RAFFLES).

Two adults from Ishigaki, ♂ March 23, ♀ June 7.

¹ This name is by many ornithologists improperly spelled, "Dendrocycna." Swainson's original spelling was "Dendrocygna."

Demiegretta ringeri STEJN.

One fine adult female, taken in Ishigaki, March 25. This skin agrees with Stejneger's description, and the northern reef heron is a valid form, differing, as pointed out by Stejneger, from the southern reef heron in its gray head and occipital crest. It is, however, not recognized by Sharpe in the Catalogue of Birds in the British Museum.

Nannocnus eurythmus (SWINH.).

Two adults from Ishigaki, ♂ taken March 25, ♀ June 10. [Nests built in reeds about two feet from the ground, containing six eggs each, were found from May 19 to July 3.]

Pyrhrherodias manillensis (MEYEN).

Six specimens, all from Ishigaki, adult ♂ June 20, adult ♀ May 20, and four nestlings June 1. [Eggs were taken from April 22 to May 19. The nests were placed on oak and other trees, at from 20 to 30 feet from the ground, and usually contained four eggs each.]

This heron was first recorded from the Yayeyama Islands by Stejneger in 1891, who doubtfully referred¹ it to *Ardea purpurea* Linn., but pointed out differences from that species. At that time the relationship of the two members of this genus, *purpurea* and *manillensis*, was not understood. The Ishigaki specimens appear to be typical *P. manillensis*, though I have had but few skins for comparison.

Turnix taigoor (SYKES).

Four specimens from Ishigaki, adult ♂ taken April 25 (wing 77), adult ♀ April 25 (wing 84), and two chicks taken April 12. [Eggs, four in a clutch, were taken from March 17 to July 3.] This is the *Turnix blakistoni* (Swinh.) of Stejneger (Proc. U. S. Nat. Mus., 1886, Vol. IX, p. 635). Dr. Stejneger now agrees with me in the identity of these two forms.

Sphenocercus medioximus,² sp. nov.

TYPE. — Mus. Comp. Zool., No. 37,349.

Two adults from Ishigaki, ♂ taken March 9, ♀ March 7. Specimens were secured on this island from February 2 to June 5. [Nests containing two eggs each were found on trees at from six to ten feet from the ground, between April 25 and June 2.]

¹ Proc. U. S. Nat. Mus., 1891, Vol. XIV, p. 493.

² *Medioximus*, middlemost, holding a middle place.

Characters. — Nearest in color to *S. permagnus* (Stejn.) from the middle group of the Liu Kiu Islands, but much smaller, being little larger than *S. formosæ* (Swinh.) of Formosa.

Color. — Type, adult ♂. Forehead yellowish oil green, slightly shaded with chestnut toward crown; rest of upper parts dark oil green, the feathers of the cervix, sides of head and neck and upper back, pale gray below the green tips, this color showing through a little, giving a hoary cast to these parts; rump and upper tail coverts a little brighter; primaries slaty black with a perceptible greenish tinge toward ends, the three outer ones narrowly edged with yellowish; secondaries, alula, and middle coverts slaty black somewhat washed with green; middle coverts and secondaries bordered externally with yellow; rest of wing and scapulars oil green with a slight wash of chestnut on shoulder; under parts yellowish oil green; middle of belly and striping on flanks yellowish white; under tail coverts (reaching to end of tail) dark oil green broadly edged with straw yellow; rectrices above olive green, below slaty black with grayish tips; under surface of wing slaty.

Adult ♀, similar to the ♂ but duller in color throughout, and lacking the slight chestnut suffusion on crown and shoulders, and with the grayish tinge of cervix, upper back, and sides of head much less pronounced.

Measurements. — Adult ♂, type, wing 193.5; tail 133; tarsus 26.8; exposed culmen 19. Adult ♀, topotype, wing 192; tail 129; tarsus 26; exposed culmen 18.6.

The Green Pigeon differs in the islands as follows: *S. permagnus* is confined to the middle group of the Liu Kius, while *S. medioximus* is peculiar to the southern group; *S. formosæ* belongs further south still, to the island of Formosa.

Stejneger's type of *S. permagnus* is in the Museum at Tokyo, and I have not seen specimens of the species. In addition to the species here described being intermediate in size between *S. permagnus* and *S. formosæ*, it differs slightly in color from either of the two. In *S. medioximus* two sets of wing coverts are bordered with yellow, and the male has a decided wash of chestnut on both crown and shoulders. Stejneger especially describes his type as having only one set of coverts "the outer great coverts" edged with yellow. If the type of *S. permagnus* be a male, as was supposed, then the chestnut wash on the crown and shoulders of *S. medioximus* is a distinctive character, and yet again very different from the strong coloring of these parts in *S. formosæ*.

Chalcophaps indica (Linn.).

Two specimens, ♂ and ♀ adults, from Ishigaki. The ♂ taken March 20, the ♀ taken June 10. [Many nests were found, containing two eggs each, usually placed in dead trees at from six to ten feet from the ground.]

The two Ishigaki skins differ slightly from two Indian specimens of true *C. indica* with which I compared them. In the Liu Kiu birds the band on the

lower back between the two gray bands is not coppery bronze, but is dull black, almost without metallic lustre, and the male has a much greater amount of gray on back and upper neck.

A green-winged dove was described by Swinhoe from Formosa as *C. formosana*, but is not recognized as distinct from *C. indica* by Count Salvadori, in the British Museum Catalogue (Vol. XXI. pp. 514-520).

***Megascops elegans* (CASSIN).**

Two adults from Ishigaki, ♂ taken March 25, ♀ March 23. Specimens were taken from March 1 to June 3. [Eggs, two in a clutch, were taken from holes in trees, seven to fifteen feet from the ground, from May 14 to June 27.]

***Ninox japonica* (TEMM. & SCHL.).**

Three specimens from Ishigaki, adult ♂ taken April 20, adult ♀ April 15, and a half-grown young, no date. These skins agree with Japanese specimens. The wing of the adult ♂ measures 215, of the adult ♀ 210.

***Accipiter gularis* (TEMM. & SCHL.).**

Three specimens, a ♀ (?) not in full adult plumage taken June 1, an adult ♂ March 25, and a downy nestling June 27, all from Ishigaki.

***Butastur indicus* (GMEL.).**

Two specimens from Ishigaki, neither in full plumage, the ♂ taken June 1, the ♀ March 23.

***Halcyon coromanda rufa* (WALLACE).**

Two specimens from Ishigaki, adult ♂ and ♀, both taken April 25. Specimens were secured in Ishigaki and Taketomi from April 5 to June 10. [Eggs, three in a clutch, were collected from June 1 to June 21. The nests were in holes in trees at about ten feet from the ground.] I follow Dr. Stejneger in provisionally referring the Liu Kiu Ruddy Kingfisher to this form.

***Anthus maculatus* HODGS.**

One female taken in Ishigaki, April 7.

***Motacilla lugens* KITTL.**

One adult ♂ in full spring plumage, taken in Ishigaki, June 1. This seems rather a late date for *M. lugens* to be in the Liu Kiu Islands.

Hypsipetes pryeri STEJN.

Five specimens from Ishigaki, an adult ♂ taken Feb. 29, an adult ♀ April 30, and three recently hatched young April 21. [Skins were also obtained in Kabama, and eggs, four in a clutch, were taken from April 2 to June 25.]

Merula pallida (GMEL.).

Two adults from Ishigaki, ♂ February 20, ♀ May 1. (Many specimens were taken in Ishigaki up to June 20.)

Merula chrysolaus (TEMM.).

Two specimens from Ishigaki, adult ♂ May 7, adult ♀ February 18. [Skins were collected in Ishigaki between February 18 and June 7.]

Merula obscura (GMEL.).

Two adults from Ishigaki, ♂ February 22, ♀ March 1. [Obtained in Ishigaki between February 20 and March 1.]

Monticola solitaria (MÜLL.).

One adult ♀, Ishigaki, March 23.

Terpsiphone illex,¹ sp. nov.

TYPE. — Mus. Comp. Zool. No. 37,363.

Two specimens from Ishigaki, an adult ♂ April 25, and an adult ♀ May 31. [Specimens were taken between April 25 and June 20. Eggs, four in a clutch, between May 12 and June 13.]

Characters. — Nearest to *T. princeps* (Temm.) of China and Japan, but smaller; rectrices narrower and squarer at ends; wing shorter; primaries very short and decidedly narrower and more pointed at ends; *wing formula different* — 4th primary longer than 5th (these two equal in *T. princeps*, or 4th slightly shorter than 5th); feathers of crest in the ♂ all narrower, less rounded; colors much as in *T. princeps*, except less white in axillas and lining of wing; feathers of crest in the ♂ steel blue instead of purplish; sides more heavily washed with brown.

The ♀ differs from the ♀ of *T. princeps* in the same manner as does the ♂, *i. e.*, it is smaller; in having narrower, shorter, more pointed primaries; narrower rectrices; crest feathers narrower and bluer, less purplish in color.

¹ *Illex*, alluring, enticing.

Color.—Adult ♂, head all round, throat, and jugulum blue black, rather more purplish on throat than on crown; back and scapulars glossy prune purple; upper tail coverts and tail blue black; wings black edged with purplish brown; middle of belly and under tail coverts white; sides and flanks heavily washed with dark purplish brown; axillas dull brownish black with white tips; under primary coverts black; under wing coverts white streaked with pale brown.

Female, crown blue black; sides of head and cervix dark gray; throat dark gray becoming paler on jugulum; back chestnut, many of the feathers glossy purplish maroon at ends; tail dark purplish brown; wings hair brown edged with hazel, deeply so on secondaries and tertiaries; middle of belly and under tail coverts white; sides and flanks washed with purplish brown; lining of wing as in the ♂, except primary coverts are hair brown instead of black.

Measurements.—Adult ♂, type, wing 88; tail, to end of middle rectrices 246.5, to end of longest other rectrices 113; greatest width of outer rectrix, 8.8; tarsus 14.4; exposed culmen 15.4.

Adult ♀, topotype, No. 37,364, wing 82; tail 80; tarsus 14; exposed culmen 15.4; width of outer rectrix 9.2. [In adult males of *T. princeps* the wing ranges from 92 to 94, and the greatest width of the outer rectrix is 11.4. In the adult females the wing measures from 88–90, and the greatest width of the outer rectrix is 12.]

Remarks.—This appears to be the first record of a Paradise Flycatcher from the Liu Kiu Islands. Besides being considerably smaller than a *T. princeps*, it differs noticeably in its short, narrow, pointed primaries and narrow rectrices, and in having the 4th primary longer than the 5th. Like so many of the breeding birds of these islands, it is a well-marked island species.

Zanthopygia owstoni,¹ sp. nov.

TYPE.—Mus. Comp. Zool., No. 37,367.

One male from Ishigaki, June 20.

Characters.—Nearest to *Z. narcissina* of Japan, but wing much shorter, due chiefly to the shortening of the primaries; *wing formula different*—2nd primary shorter than 6th, 3rd about equal to 5th, 4th longest. In *Z. narcissina* the 2nd primary is much longer than 6th, 3rd equals 4th, these two longest and longer than 5th. In color the island bird is very different, the back is dark green, not black, the yellow frontal band extends all the way across base of culmen, the throat and breast are clear gamboge yellow, not orange.

From *Z. zanthopygia* (Hay) the species can be distinguished by its yellow eyebrow (white in *Z. zanthopygia*) and differently marked wing.

Color.—Male, apparently fully adult (♀ unknown), narrow frontal band, extending directly across base of culmen and thence over eye to the supra-auricular region, gamboge yellow; pileum, cheeks, back, and scapulars dusky

¹ Named in honor of Mr. Alan Owston.

olive green ; rump bright gamboge yellow ; upper tail coverts and tail black ; wings dark hair brown, the lesser coverts dull, dark plumbeous ; a large white wing patch, formed by the white color of the middle and most of the greater coverts ; one or two (on each side) of the longer tertials narrowly edged with whitish for the basal half of the outer web ; throat, jugulum, and breast bright gamboge yellow, becoming yellowish white on belly and under tail coverts ; sides and flanks washed with olive green ; lining of wing and narrow inner margin of wing feathers, below, white.

Measurements.—Type ♂, wing 67 ; tail 45 ; tarsus 15.8 ; exposed culmen 10.2 ; distance from tip of longest secondary to tip of longest primary about 15.

Remarks.—In Proc. U. S. Nat. Mus., 1887, Vol. X, pp. 406-407. Stejneger pointed out the structural differences between the Liu Kiu species and *Z. narcissina* ; he, however, had but one young example of the island species, and on this account refrained from giving it a name. The one skin obtained by Zensaku bears out all the structural characters, and besides shows marked color differences from either *Z. narcissina* or *Z. zanthopygia*.

The type of *Z. owstoni*, a male, appears to be in full breeding plumage, and if so, the dark olive green color of the back is unlike any other species, and would alone distinguish the Liu Kiu form.

***Cisticola brunniceps* (TEMM. & SCHL.).**

Two adults from Ishigaki, ♂ taken March 7, ♀ June 1. The fantail warbler is said to be the most abundant bird in the islands. [It builds its nest in grass a foot or two above the ground. Eggs, as many as seven in a clutch, were taken from March 25 to June 30.]

***Cettia cantillans* (TEMM. & SCHL.).**

One adult ♀ from Ishigaki, March 5. [Six specimens were taken on Ishigaki between March 5 and April 7.]

***Cettia cantans* (TEMM. & SCHL.).**

Two specimens from Ishigaki, ♂ taken March 25, ♀ April 6. [Specimens were secured between February 18 and April 6.]

***Hirundo rustica gutturalis* (SCOP.).**

Two adults from Ishigaki, ♂ April 4, ♀ April 3, 1899. [Four birds in all were obtained on the island between April 2 and April 5.]

***Pericrocotus tegimae* STEJN.**

A pair of adults from Ishigaki, the ♀ taken June 20, the ♂ June 10. These specimens agree exactly with Stejneger's type.

Lanius bucephalus TEMM. & SCHL.

One adult ♀ from Ishigaki, May 10, 1899. I have compared this skin with an extensive series from Japan, and find it identical with mainland birds of the same sex in corresponding plumage.

Parus stejnegeri,¹ sp. nov.

TYPE. — Mus. Comp. Zool., No. 37,392.

Three specimens from Ishigaki, adult ♂ February 27, adult ♀ June 1, and a nestling June 7.

Characters. — Not nearly related to any known species; general coloration gray-blue, black, and white; under tail coverts mostly black; outer rectrices with no white, except a *very narrow* tip on the outer pair; no white patch on nape, a few feathers of this region with partly concealed white spots only noticeable when the feathers are disturbed; general coloration of nestling greenish and dull yellow, showing the probable affinities of this species to some of the yellow and green titmice, such as *P. jerdoni*, *P. inseparatus*, etc., which have black under tail coverts and but little white in the tail.

Color. — Adult ♂ type, a large white auricular patch; rest of head, throat, jugulum, and neck glossy blue-black; a few feathers on middle of hind neck with small semi-concealed white spots; back, rump, and upper tail coverts dark plumbeous, slightly paler on lower rump; scapulars and broad edgings to greater and lesser wing coverts plumbeous; some of the greater coverts tipped with drab-gray, forming a broken and inconspicuous wing bar; rest of wing grayish black, primaries edged with light plumbeous, secondaries with greenish gray, and tertials rather more broadly on outer webs with grayish white; primary coverts greenish gray; a broad black stripe down middle of under parts, from jugulum to under tail coverts; sides and flanks dull olive gray, much paler and more drabby along edges of central black stripe and below the black of jugulum and sides of neck; under tail coverts black, slightly edged and tipped with dark plumbeous, one or two of the shortest lateral ones a little marked with white; rectrices, below blue-black, above, broadly edged on outer webs with dark plumbeous, the central pair mostly of this color, on both webs; two outer rectrices with very narrow white tips, 2 mm. deep; bend of wing black; under primary coverts black tipped with white; axillars mostly white; under sides of primaries grayish white on edges of inner webs.

Adult ♀, topotype, No. 37,393, similar in markings to the male, all the colors duller and lateral under tail coverts more noticeably marked with white.

Nestling, topotype, about two-thirds grown, auricular patch olive yellow; head, back, and throat dusky olive green, darkest on top of head and sides of throat; a blackish line down middle of belly; sides, flanks, and under tail

¹ Named in honor of Dr. Leonhard Stejneger.

coverts dull olive yellow; wings grayish hair brown, scapulars and lesser coverts dull grayish olive, tips of greater coverts yellowish, forming a wing bar; primaries and secondaries edged with greenish gray; tail grayish hair brown edged with greenish gray, outer rectrices *barely* tipped with whitish.

Measurements. — Adult ♂ type, wing 62; tail 55.5; tarsus 18.2; exposed culmen 11. Adult ♀, topotype, No. 37,393, wing 60; tail 50; tarsus 18; exposed culmen 10.5.

***Corvus macrorhynchus levaillantii* (LESSON).**

Four specimens, all from Ishigaki, adult ♂ March 25, adult ♀ March 28, and two young from the nest June 10. [Eggs, four in a clutch, were taken April 11 to June 10.]

***Sturnia pyrrhogenys* (TEMM. & SCHL.).**

One male from Ishigaki, June 1, 1899.

***Zosterops loochooensis* (TRISTRAM).**

Two specimens from Ishigaki, adult ♂ March 13, adult ♀ April 6. [Abundant on Ishigaki and Kuroshima. Skins were taken from February 18 to June 7, and eggs, four in a clutch, April 2 to June 25.]

A careful comparison of these two specimens with numerous examples of *Z. simplex* and *Z. japonica* proves the Liu Kiu form to be a distinct island race, in spite of the doubts cast upon it in the latest review of the group.¹ But as no adequate description of it appears to have been published, I append the following:—

Characters. —Nearest to *Z. simplex* of China, but bill heavier, wing longer; of a brighter green color above, and brighter yellow color below; the species differs from *Z. japonica* in slightly shorter wing and in the color of the sides and flanks, which lack the strong vinous brown of this region in the Japanese species, and also in the primaries, being very short and narrow at tips (a character presented by many of the species of birds peculiar to the Liu Kiu Islands); wing formula, 1st primary about equal to 6th, shorter than 5th, 2nd equal to 4th, 3rd longest.

Color. — Whole upper parts including margins of wing and tail feathers yellowish oil green, frontal region slightly yellower; wings and tail black (except for the green margins of the feathers); orbital ring silky white; a dusky spot below and in front of eye; chin and throat lemon yellow; breast and belly soiled whitish, faintly washed with yellowish along median line and with pale écreu drab on sides and flanks; thighs yellowish white in front, dusky oil green behind; under tail coverts lemon yellow; bend of wing lemon yellow; alula black; lining of wing and axillas pale yellow; narrow inner margins to wing feathers below whitish.

¹ Finsch, O. *Zosteropidae*. *Das Tierreich*, 1901, 15, p. 20.

Measurements. — Adult ♂, No. 37,390, wing 57 ; tail 39.5 ; tarsus 18 ; exposed culmen 11.2 ; distance from tip of longest secondary to tip of longest primary 11.

Adult ♀, No. 37,391, wing 57 ; tail 40 ; tarsus 18 ; exposed culmen 11 ; distance from tip of longest secondary to tip of longest primary 11.5.

***Emberiza spodocephala* PALL.**

One male, not in full plumage, from Ishigaki, April 8.

***Passer montanus saturatus* STEJN.**

One adult ♂ from Ishigaki, June 30. This specimen differs from the type of *P. saturatus* only by slightly paler colors, due to the more abraded condition of its plumage. [The bird was common in the island, and was breeding in the roofs of the houses. Eggs, seven in a clutch, were taken March 20 to June 25.]

***Coccothraustes coccothraustes japonicus* (TEMM. & SCHL.).**

One female from Ishigaki, March 7.

9820-13

The following Publications of the Museum of Comparative Zoölogy
are in preparation:—

Reports on the Results of Dredging Operations in 1877, 1878, 1879, and 1880, in charge of ALEXANDER AGASSIZ, by the U. S. Coast Survey Steamer "Blake," as follows:—

E. EHLERS. The Annelids of the "Blake."

C. HARTLAUB. The Comatulæ of the "Blake," with 15 Plates.

H. LUDWIG. The Genus *Pentacrinus*.

A. MILNE EDWARDS and E. L. BOUVIER. The Crustacea of the "Blake."

A. E. VERRILL. The Alcyonaria of the "Blake."

Reports on the Scientific Results of the Expedition to the Tropical Pacific, in charge of ALEXANDER AGASSIZ, on the U. S. Fish Commission Steamer "Albatross," from August, 1899, to March, 1900, Commander Jefferson F. Moser, U. S. N., Commanding.

Illustrations of North American MARINE INVERTEBRATES, from Drawings by BURKHARDT, SONREL, and A. AGASSIZ, prepared under the direction of L. AGASSIZ.

LOUIS CABOT. Immature State of the Odonata, Part IV.

E. L. MARK. Studies on *Lepidosteus*, continued.

" On *Arachnactis*.

R. T. HILL. On the Geology of the Windward Islands.

W. McM. WOODWORTH. On the *Bplolo* or *Palolo* of Fiji and Samoa.

A. AGASSIZ and A. G. MAYER. The *Acalephs* of the East Coast of the United States.

AGASSIZ and WHITMAN. Pelagic Fishes. Part II., with 14 Plates.

J. C. BRANNER. The Coral Reefs of Brazil.

Reports on the Results of the Expedition of 1891 of the U. S. Fish Commission Steamer "Albatross," Lieutenant Commander Z. L. TANNER, U. S. N., Commanding, in charge of ALEXANDER AGASSIZ, as follows:—

A. AGASSIZ. The Pelagic Fauna.

" The Echini.

" The Panamic Deep-Sea Fauna.

K. BRANDT. The *Sagittæ*.

" The *Thalassicolæ*.

C. CHUN. The Siphonophores.

" The Eyes of Deep-Sea Crustacea.

W. H. DALL. The Mollusks.

H. J. HANSEN. The Cirripeds.

W. A. HERDMAN. The Ascidians.

S. J. HICKSON. The Antipathids.

W. E. HOYLE. The Cephalopods.

G. VON KOCH. The Deep-Sea Corals.

C. A. KOFOID. *Solenogaster*.

R. VON LENDENFELD. The Phosphorescent Organs of Fishes.

H. LUDWIG. The Starfishes.

J. P. McMURRICH. The Actinarians.

E. L. MARK. *Branchiocerianthus*.

JOHN MURRAY. The Bottom Specimens.

P. SCHIEMENZ. The Pteropods and Heteropods.

THEO. STUDER. The Alcyonarians.

M. P. A. TRAUSTEDT. The Salpidæ and Doliolidæ.

E. P. VAN DUZEE. The Halobatidæ.

H. B. WARD. The Sipunculids.

H. V. WILSON. The Sponges.

W. McM. WOODWORTH. The Nemerteans.

" The Annelids.

PUBLICATIONS
OF THE
MUSEUM OF COMPARATIVE ZOÖLOGY
AT HARVARD COLLEGE.

There have been published of the BULLETINS Vols. I. to XXXV.; of the MEMOIRS, Vols. I. to XXIV.

Vols. XXXVI., XXXVII., and XXXVIII. of the BULLETIN, and Vols. XXV., XXVI., and XXVII. of the MEMOIRS, are now in course of publication.

The BULLETIN and MEMOIRS are devoted to the publication of original work by the Professors and Assistants of the Museum, of investigations carried on by students and others in the different Laboratories of Natural History, and of work by specialists based upon the Museum Collections and Explorations.

The following publications are in preparation:—

Reports on the Results of Dredging Operations from 1877 to 1880, in charge of Alexander Agassiz, by the U. S. Coast Survey Steamer "Blake," Lieut. Commander C. D. Sigsbee, U. S. N., and Commander J. R. Bartlett, U. S. N., Commanding.

Reports on the Results of the Expedition of 1891 of the U. S. Fish Commission Steamer "Albatross," Lieut. Commander Z. L. Tanner, U. S. N., Commanding, in charge of Alexander Agassiz.

Reports on the Scientific Results of the Expedition to the Tropical Pacific, in charge of Alexander Agassiz, on the U. S. Fish Commission Steamer "Albatross," from August, 1899, to March, 1900, Commander Jefferson F. Moser, U. S. N., Commanding.

Contributions from the Zoölogical Laboratory, Professor E. L. Mark, Director.

Contributions from the Geological Laboratory, in charge of Professor N. S. Shaler.

These publications are issued in numbers at irregular intervals; one volume of the Bulletin (8vo) and half a volume of the Memoirs (4to) usually appear annually. Each number of the Bulletin and of the Memoirs is also sold separately. A price list of the publications of the Museum will be sent on application to the Librarian of the Museum of Comparative Zoölogy, Cambridge, Mass.
